Valve Seats. Valve seats take the place of valves in some of the pot-valve designs used on heavy-duty pumps such as those which pump drilling mud (Fig. 19-8). Ball valves are also used in pumps; in some cases the ball is rubber; in other cases it is metal engaging a rubber valve seat.

Line Check Valves. Line check valves are similar in general to pump valves but are usually contained in a disk holder. Ball checks are also used.

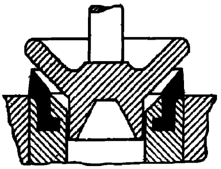

FIG. 19-8. Valve seats.

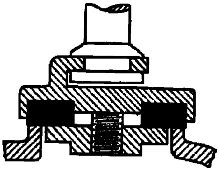

FIG. 19-9. Disk holder.

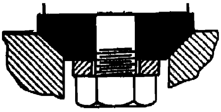

FIG. 19-10. Hydrant valve.

Disks for Globe and Angle Valves. Disks for globe and angle valves are contained in disk holders (Fig. 19-9) which have either round or oval center pins and are swiveled to prevent rotation of the disk when closed. Disks are usually hard rubber with asbestos fiber present as reinforcement to the extent of from 10 to 70 per cent. They are employed on steam service up to 150 psi, but at the higher pressure range tend to undergo too much indentation by the valve seat, with consequent cracking and scouring out by escaping steam. Laminated or solid phenolic resins are longer lived but require a more accurate finish in the valve seat. Metal-clad disks are also used.

Faucet Bib Washers. Faucet bib washers are similar to globe-valve disks but softer, *i.e.*, in the semiebonite range. A good faucet, like a good globe valve, will have its disk holder swiveled so that the disk does not rotate as it makes contact. Hydrant valves (Fig. 19-10) are modified globe valves; they employ beveled disks of leather, semihard rubber, or duck-inserted rubber.

Flap Valves (Fig. 19-11). Flap valves cut from leather or rubber are also used as check valves. Some soft pump valves of conventional design are employed as flap valves by holding them down in the center and forcing the edges to lift. A disadvantage of flap valves is that they fail by fatigue cracking.

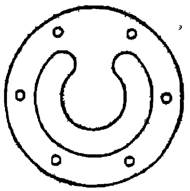

Fig. 19-11. Flap valve.

SLIDING-CONTACT PACKINGS—GENERAL

Sliding-contact packings differ in several important respects from gaskets.

1. They do not make intimate contact with the sliding member, since such contact would lead to destruction of one or both surfaces. A badly fitting packing makes dry contact over a portion of its area, leading initially to high friction and wear, but this condition tends to correct itself as the high spots wear away.

2. Over all that portion of the interface which is not in dry contact there is a clearance which is filled with the fluid being packed. This fluid is constantly being lost on the low-pressure side and replenished on the high-pressure side. There is no such thing as a "leakless" sliding-contact packing, although the leakage under certain conditions may be so low that it is not detected.*

3. In an ideal packing, no portion of which is in dry contact, leakage conforms to the laws of fluid flow, which means that it is proportional to pressure differential and to the width of the escape path (*i.e.*, circumference in the case of a shaft or rod packing), inversely proportional to fluid viscosity and to the length of escape path (*i.e.*, packing depth), and proportional to the third power of the clearance. In a badly fitting packing the clearance is reduced to a series of channels, but leakage is relatively high owing to the thickness of these channels.

4. Relative motion has little influence on leakage provided it does not cause a change in clearance. However, if a rotary shaft at high speed is subject to gyration (generally known as "runout"), it will batter an opening through the packing, which is larger than itself, and the fluid leakage may under such conditions become uncontrollable. Similar effects result from a reciprocating shaft subject to lateral thrust (generally known as "weave") or, in the case of axial seals, a tipping of the plane of one ring with reference to that of the other ring, provided these movements occur at a rate too rapid for the packing to respond.

5. In an ideal packing friction conforms to the laws of fluid shear, *viz.*, proportionate to both packing width (*i.e.*, circumference) and depth, to viscosity, to speed of relative motion (in feet per minute), and inversely proportional to clearance. The materials of which the packing and sliding members are composed are without influence. It will be noted that three of the factors that make for high friction, *viz.*, packing depth, viscosity, and low clearance, are also included in those which make for low leakage. As long, therefore, as circumference and speed are fixed, there is an inverse relationship between leakage and friction.

In the badly fitting packing, the laws of solid friction apply over a portion of the area, *viz.*, proportionate to the area that is in dry contact, to unit load over this area, and to the coefficient of friction between the material of the packing and the sliding member. Speed and fluid viscosity are without influence on this portion of the total friction. In general, the friction of a badly fitting packing is much higher than that of an ideal packing owing to the high unit loads employed in an effort to depress the high spots and reduce the leakage channels.

6. In the case of an ideal packing, the pressure of packing against the sliding member need be enough only to overcome the pressure of the fluid in the clearance, which averages midway between the high-side and low-side pressures. Thus, in an ideal packing that is leaking to the atmosphere, a unit load equal to half the fluid

---

* It has been recently brought out that certain combinations of fluid viscosities, clearances, and surface speeds give rise to vortices in the contained fluid which are "leakless" against low-pressure differentials. This does not detract from the general statement.

pressure is sufficient to keep the packing from blowing away. This, it will be noted, is just half the minimum required to prevent leakage, *i.e.*, to make the packing function as a gasket. In practice, it is not possible to avoid the application of some excess pressure, which leads to development of dry contact over a portion of the area, and the packing is no longer "ideal." The closer it is possible to maintain the packing load at the theoretical 50 per cent value, the more nearly do ideal conditions obtain.

In the case of a badly fitting packing, high unit loads are necessary initially to reduce leakage channels. The amount of such necessary excess pressure is governed by the initial roughness and by the ability of the packing material to smooth up under applied pressure. As the packing wears in to a condition approaching ideal, such excess loads can be dispensed with.

7. The heat developed within a packing is proportional to the product of friction and surface speed. The temperature of the packing rises until the rate of heat dissipation equals the rate of heat generation. Temperature can be held down by improved means of heat dissipation, such as water-cooled shafts, water-jacketed stuffing boxes, etc., but the most effective way to reduce temperature is to adjust for a higher leakage rate and a correspondingly lower friction.

High temperature in a packing may lead to excessive thermal expansion with further increase in load and ultimate seizure. If the packing is so constructed that this thermal expansion does not occur or does no harm, temperature will eventually reach a ceiling owing to lowered viscosity of the escaping fluid and consequently lower friction.

From the foregoing, it is clear that the two major requirements of a successful sliding-contact packing are (1) that its working face should conform as accurately as possible to that of the sliding member or should acquire this condition within a reasonable time after starting and (2) that means should exist for developing the unit load normal to the sliding surface which is necessary to control clearance. Other requirements are (3) that it should be composed of material that will not damage the sliding member during the process of wearing in to a fit, (4) that it should be capable of withstanding without injury the heat resulting from packing friction, and (5) that it should not be attacked by or contaminate the fluid being packed. A summary of the most widely used sliding-contact packings is shown in Tables 19-5 and 19-8.

The stuffing box is the oldest known means of controlling packing load and has heretofore, until very recently, controlled the development of sliding-contact packings. In the stuffing box, the load is applied axially by advancing the gland; the packing must, therefore, be of a type that will transmit the load at right angles, *i.e.*, must be capable of spreading radially. Originally this limited stuffing-box packings to soft materials such as braided yarns and rubber compounds, and these were supplied generally in square cross section and in the form of coils, helices (incorrectly known as "spiral"), and cut rings. However, the development of molded conical (Fig. 19-26*d*) and V-ring (Fig. 19-26*c*) cross sections has made it possible to employ a number of more rigid materials in stuffing boxes. In the conical design, lateral spreading is effected by the principle of the inclined plane, in the V ring by that of the toggle joint.

Contrary to popular impression, the gland does not exert a following load on the packing unless it is driven by springs. More usually, the packing load is maintained by the escaping fluid acting in two ways: (1) along the rod or shaft, trying to drive the packing radially outward, or (2) along the front wall of the stuffing box, trying to drive the packing axially backward, *i.e.*, against the gland. Since the latter is the higher pressure and is transmitted radially by the packing, it overpowers the former, especially as the gland is approached. Removal of a worn stuffing-box packing will almost always reveal that the ring next to the gland has been forced against the rod or shaft most strongly, has been worn the most, and has done most of the work.

A weakness of all stuffing boxes is that the packing, being wholly confined, is subject to unstable thermal expansion and seizure if overtightened. This can be minimized by effective cooling, by the employment of materials of low coefficient-of-volume expansion, by providing voids within the set into which expansion can take place harmlessly, or by providing a fusible binder which escapes harmlessly from the box if overexpansion occurs. The opposite type of weakness is also encountered, *viz.*, coarse clearances at back and front of the box, through which packing tends to extrude unless prevented by end rings of strong construction but of no packing value, known as "antiextrusion rings."

Since the gland has no function other than to develop an initial load normal to the rod or shaft, it can frequently be dispensed with. In the O-ring packing (Fig. 19-26*b* or 19-34*c*), the initial load is effected by crowding the ring into a groove, thereby deforming it into an ellipse; thereafter the packing is tight against all fluid pressures. In the flange, or "hat," packing (Fig. 19-26*e*) and in the "cup" packing (Fig. 19-34*e*), initial normal load is developed by molding the lip to a slight flare; fluid pressure invading the interior of the packing supplies the continuing load. Fluid load can be supplemented by a spring as in the radial seal (Fig. 19-32*a*,*b*). U packings (Fig. 19-26*f*) are similar but pack against both the rod and outside circumference of the groove. Packings that are capable of contracting radially can be installed in oversize grooves; fluid pressure acting on the outer perimeter develops the necessary packing load, as in the case of the metal packing (Fig. 19-31). In the case of piston packings, fluid pressure admitted to the inside circumference forces the packing outward, as in the rectangular piston ring (Fig. 19-34*a*). In these designs the packings are not closely confined. The effect of thermal seizure is therefore minimized.

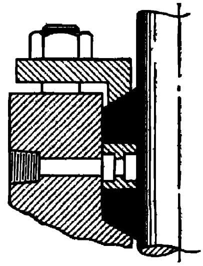

FIG. 19-12. Lantern ring.

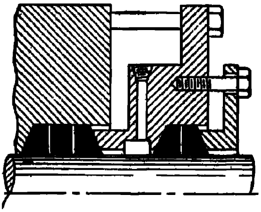

FIG. 19-13. Tandem gland.

Not all sliding-contact packings used to pack rotating shafts operate on cylindrical surfaces. The axial seals (Table 19-5) operate on flat faces. They are subject to the same laws of packing operation as stuffing-box packings but can generally be made to give better performance by careful attention to design and finish.

Although leakage is a necessary characteristic of all sliding-contact packings, there is a way by which any leakage of the fluid being handled can be avoided for the full life of the packing. This consists in injecting into the packing a liquid, known as a "sealing liquid," at a pressure higher than that of the fluid. Under these conditions the flow is reversed, the sealing liquid flowing into the apparatus in addition to escaping to the atmosphere. The means employed to inject sealing liquid (sometimes erroneously referred to as "lubricant") into a stuffing box are generally some modification of the "lantern ring" (Fig. 19-12) or "tandem gland" (Fig. 19-13). In a similar manner, sealing fluid can be introduced into the space between two radial or axial seals or groove packings.

Sometimes one of the above devices is equipped with two connections, one to introduce sealing liquid and the other to bleed away part of it, with incidental removal of some of the generated heat within the packing set. Such an arrangement is called a "circulation fitting." A lantern ring located at the bottom of a packing set is known as a flushing connection and is sometimes employed when there are no objections to the introduction of large volumes of sealing fluid into the apparatus.

Sealing-liquid injection is indicated in examples such as the following:

1. All packings against gases, which, because of low viscosity, leak excessively. This includes all vacuum applications, the steam engine, steam turbine, gas compressor, and all high-pressure autoclaves in which the agitator enters the gas space at the top. It is of interest to note than an original Watt patent for the steam engine called

for seal-oil injection into the piston rings, a rational arrangement which unfortunately has been forgotten by most of his successors.

2. All packings for liquids of very low viscosity or high volatility, such as gasoline, water, etc., under conditions of high speed, high pressure, or both. Instances are the injection of lube oil into the stuffing boxes of oil refinery pumps handling propane, etc., the injection of grease into ram packings operating against high-pressure water, the injection of oil between double axial seals on water pumps.

3. All packings for liquids containing large amounts of dissolved or suspended matter, which tends to crystallize or filter out in their passage through the packing. Instances are the water sealing of centrifugal-pump boxes handling caustic soda, etc., and the water sealing of boxes of hydraulic turbines operating on muddy water.

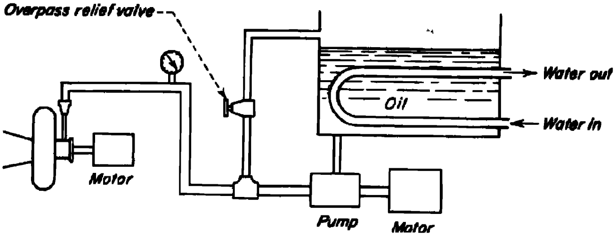

FIG. 19-14. Independent seal-oil system.

4. All packings for fluids of any kind that are poisonous, corrosive, or too valuable to lose. Instances are pure-gasoline injection into the boxes of pumps handling anhydrous hydrogen fluoride in the "alkylation" process, oil injection into ammonia-compressor rod packings, etc.

The sealing medium can be injected continuously or periodically, as by a pulsating lubricator or grease gun, but the latter generally is ineffective as the fluid starts to invade the stuffing box as soon as the original injection pressure has died down. The ideal arrangement introduces the sealing liquid continuously at a pressure only slightly higher than that of the fluid, whereby minimum contamination of the fluid by the sealing liquid is obtained. Means to effect this are the independent seal-oil system (Fig. 19-14), connected directly or through a differential regulator (Fig. 19-15), spring-loaded grease cup (Fig. 19-16), oil bottle (Fig. 19-17), and differential cylinder (Fig. 19-18).

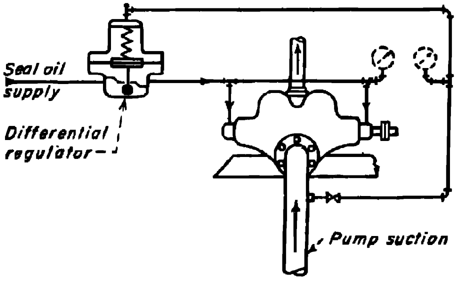

FIG. 19-15. Differential regulator.

Another disagreeable but unavoidable characteristic of sliding-contact packings is that, at the conclusion of operations, fluid is always left trapped in the clearances and in an abnormally favorable condition to cause corrosion of the moving member assuming that this is metal and that the fluid is one, such as water, in which the metal has a measurable solution pressure. In fact, many fluids that are quite incapable of corroding metals in open vessels will corrode them quite freely when trapped in the clearance between packing and the metal. This phenomenon, known as "crevice

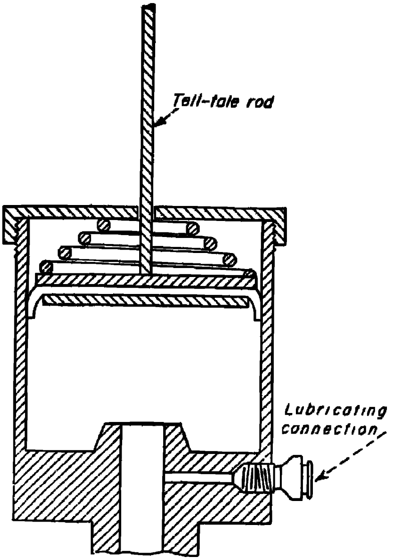

Fig. 19-16. Spring-loaded grease cup.

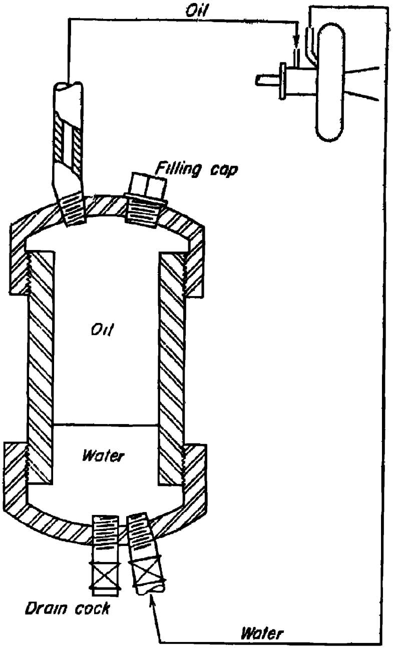

Fig. 19-17. Oil bottle.

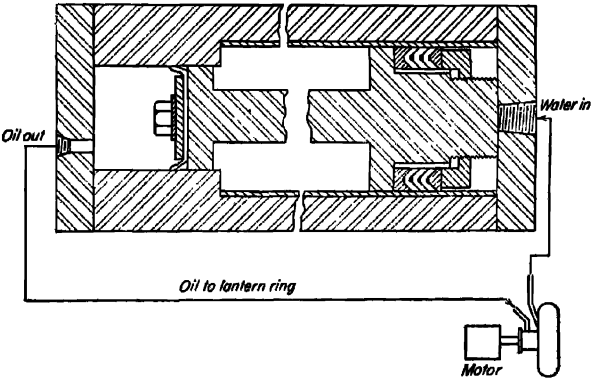

Fig. 19-18. Differential cylinder.

corrosion," is not fully understood but is believed to be associated with the formation of concentration cells within the fluid because of variable content of dissolved oxygen. The packing is usually blamed for such corrosion, but quite erroneously, unless it happens to contain some ingredient that dissolves in and promotes the acidity of the fluid (such as glycerine or free sulfur), or unless it happens to contain a substance which is a conductor and which has a solution pressure differing from that of the metal, under which conditions galvanic corrosion can result. Packing materials that are suspect in the latter connection are copper and brass reinforcements and graphite, although it must be admitted that the whole problem is complex and little understood. Oily packings or packings that have been supplied with oil during operation are much less likely to give rise to corrosion than other types. A good rule, however, in connection with all sliding-contact packings, and especially with those which are used to pack water or aqueous solutions, is to install them just prior to use and to pull them out if the equipment is to be idle for any extended period.

ROD, PLUNGER, OR RAM PACKINGS

Steam Engine. To a considerable extent, the extension of the reciprocating steam engine to progressively higher pressures and temperatures has kept pace with the development of the necessary rod packings. The first engines were packed with braided flax whose life was necessarily short. The introduction of the duck-and-rubber ring (Fig. 19-29*a*) in the late nineteenth century was a great step forward. It is still used for low-pressure steam-driven pumps and steam hammers. With the advent of steam pressures higher than 100 psi, it became necessary to develop better packings; the answer was found in asbestos. A conventional design in rolled rubberized-asbestos fabric is shown in Fig. 19-29*b*. These are made with either a hollow core or some sort of rubber core and usually present a bare asbestos surface to the rod, which is coated with glycerine and graphite. The function of the latter is to level up the surface, cut down abrasion, and, to some extent, shield the rubber layer from the action of hot cylinder oil emulsified inside the engine and carried out on the rod. For services where there is plenty of oil present, as in the case of vertical marine engines, a channel packing with a metallic lead core (Fig. 19-29*c*) is favored.

The principal weakness of these solid packings is that they must be put initially under a gland pressure greater than that of the steam since they become self-tightening only with difficulty. With the added heat caused by rod friction, they become overtight, and if the gland pressure is not reduced promptly, damage results. On a fast-moving rod, therefore, they tend to be somewhat unstable. Also, they, in spite of the use of rubber cores, etc., are not too well adapted to absorb shaft weave. These difficulties have been to some extent overcome by the molded V packings of asbestos-fabric–rubber which, being completely self-tightening, requires little or no initial gland load. Being, in effect, floating packings, they are capable of absorbing expansion derived from frictional heat and also shaft weave. They are, therefore, rapidly becoming the standard type of packing for reciprocating steam-engine piston rods and valve rods for temperatures up to 400°F.

For the higher temperatures, such as those encountered on uniflow engines, segmental metal packings of the type shown in Figs. 19-31*b*,*c*, are used exclusively, with provision for mechanical lubrication. Steam ends of pumps and steam hammers, are, in general, packed like steam engines.

The internal-combustion engine is usually single acting and therefore employs no rod packing. Exceptions are the large gas engines used for powering blowers in blast-furnace plants and compressors on natural-gas lines. Rod packings on these are of the segmental metal type with a lube-oil seal.

The reciprocating compressor is packed with the same types of packing as the steam engine. Service requirements for compressors used to recompress steam are obviously identical with those of a steam engine. The direct-driven air compressor is a particularly difficult rod-packing application because the air is hot and has a strong oxidizing effect on rubber. For this reason, it is customary to omit rubber cores when packing air compressors with the type of packing shown in Fig. 19-29*b*. Another difficulty is oil lubrication of the rod, which is generally less effective in an air compressor than in a steam engine. The larger air compressors, such as those used as blowing engines for blast furnaces, are always packed with segmental metal packing, as are the large gas compressors employed on natural-gas pipe lines; these are supplied with oil by a mechanical lubricator.

Direct-driven ammonia compressors represent a less severe service and are generally packed with duck-rubber rings with a lube-oil seal to prevent escape of gas. Most refrigerant compressors today, including those used for domestic refrigeration, are of the single-acting type and therefore employ no rod packings. Their packing problems are discussed under Piston Packings and Rotary Shaft Packings.

Compressors for hydrogen, as employed in the production of synthetic ammonia, represent a difficult application both because of the high pressures and the mobility of the gas. Compressors for oxygen and chlorine involve a complication due to the chemical reaction of these gases with packing materials and lubricants.

Air Motors. Pneumatic cylinders are employed widely as a means for transmitting power. The largest single use is the railroad air brake, but the cylinders employed on this are of the single-acting type and do not employ rod packing. Rod packings are employed on double-acting pneumatic cylinders and, since the air is cold, present no particular difficulties provided an ample supply of lubricating oil or condensed water is present for sealing purposes. Double-acting pneumatic cylinders are used for raising and lowering the locomotive reverse gear and for the pneumatic rock drill, air hoists, and air-operated valves and machinery. The most widely used packing is perhaps the duck-rubber V ring or one of its modifications. Braided asbestos is used for the smaller rod-packing applications.

The reciprocating pump represents the original, and still the largest, use for reciprocating rod and plunger packings. Types employed include square or V rings of plain rubber or other nonreinforced polymer "plastic" packings, leather, braids, metal-foil packings, rubber-fabric constructions, and combinations of these. For water, square-braided flax is the oldest and still one of the most widely used; it owes some of its effectiveness to the tendency of flax to swell in water. A similar product saturated with hard wax is used for high-pressure water in hydraulic systems. Rubber backs (Fig. 19-30*a*) and cores are employed to absorb shaft weave. Rubber or duck-rubber rings are used in conjunction with braided flax to exclude suspended matter and to prevent extrusion through clearances. Similar effects are secured by "channel" (Fig. 19-30*b*) and "braided diagonal" (Fig. 19-30*c*) combinations. Duck-rubber V rings have to some extent superseded these older types for water service. Metal-foil rings and fabric V rings bonded by oil-resistant rubbers are used for oil.

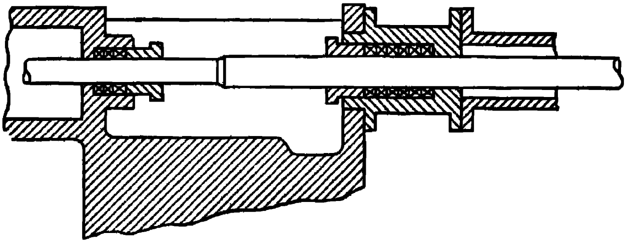

FIG. 19-19. Water gland.

Fluid sealing to exclude the product from the stuffing box is not so successful with reciprocating as with rotary pumps owing to the motion of the rod. When employed, as on heavy-duty water pumps, the "fluid" is generally a heavy grease which will make a permanent film on the rod and not be washed off on each instroke. Damage to packing caused by dissolved salts drying on the rod can be avoided by causing the rod to pass through a "water gland" (Fig. 19-19). A similar arrangement employing a suitable solvent can be used in connection with dissolved organic materials.

Water Motors. The most widely used reciprocating water motor is the hydraulic ram. Developed originally for baling cotton, it has acquired increasing importance in related fields such as oilseed extraction, plastic molding, and various metallurgical operations such as shearing, piercing, forging, and extrusion. Most hydraulic rams are single acting, vertical, and designed to return by gravity. This necessitates a packing that is almost completely self-tightening, so that friction on the return stroke may be minimized. U packings originally used for this service have been largely displaced by V rings of fabric–rubber or leather treated with hard wax.

The dead-weight type of hydraulic accumulator, used with hydraulic systems, functions alternately as a motor and a pump. The hydraulic intensifier, used to boost hydraulic pressures, is essentially a water motor, direct-connected to a pump of smaller plunger diameter. Packings for these are generally V rings.

Oil Motors. Oil hydraulic cylinders, also known as "oildraulic," deserve almost a section by themselves because of the tremendous expansion in their usage in the years prior to and during the Second World War. The advantages of oildraulic systems over hydraulic lie in freedom from scoring and corrosion of the piston rods and cylinder walls and in the possibility of using simple rotary pumps, such as gear pumps, for generating the necessary pressure. One of the earliest oildraulic power applications was the steering engine for ships. Later came the automobile and aircraft shock absorbers and the somewhat similar devices employed for absorbing gun recoil. These function alternately as pumps and as motors. More recent are oil jacks and lubricating lifts for autos, oildraulic presses, and oildraulic actuating cylinders for aircraft, dump trucks, tractors, tanks, and machine tools.

Packings employed on the large rams used for plastic-molding presses, etc., are usually duck–neoprene V rings. For the smaller double-acting piston motors, two types of rod packing are widely employed. One is a V ring of pure buna-N compound without fabric reinforcement; the other is a buna-N O ring. Single-acting piston motors of the type used for automobile brakes do not, of course, employ any rod packing, and their packing requirements are dealt with under Piston Packings. A rather complete list of reciprocating-pump, compressor and fluid-motor packing recommendations for various services is given in Tables 19-5 and 19-6.

Sleeve valves are used as boiler blowoff valves and as selector valves for use with pneumatic, hydraulic, and oildraulic motors. Packings are required to be of rigid design to permit crossing open ports. Rectangular hard-rubber rings are used for the former, V rings and U packings for the latter.

Reciprocating expansion joints and valve stems are dealt with later.

PISTON PACKINGS

A piston packing differs from a rod or plunger packing in that it packs on its outer circumference, thereby increasing the width of the leakage path and the difficulty of securing low leakage. Also it is generally not readily accessible for tightening. As a partial compensation, the leakage requirements of a piston packing are less exacting, since, at least in the case of double-acting pistons, leakage is not lost to the system but merely lessens the efficiency of the equipment.

Steam engines, internal-combustion engines, and gas compressors invariably use metal piston rings in grooves. In the smaller cylinders, these are merely cast-iron rings with a bevel cut (Fig. 19-34*a*). They are made larger than the cylinder diameter to give an initial pressure but in action derive their effective pressure from steam or gas getting into the groove beneath the ring and forcing it out against the lesser pressure of escaping steam or gas along the working face. To pack effectively, they require a liquid seal which is derived from condensed steam or from lube oil, the latter being either atomized into the cylinder or fed through appropriate ports in the piston. Larger units of these types have segmental piston sets (Fig. 19-34*f*).

Air-motor pistons are sometimes packed with metal rings, as in the pneumatic rock drill, but more generally are packed with one or two cups, according to whether the cylinder is single or double acting (Fig. 19-34*e*). The cups are of leather or of oil-resistant rubber, with or without reinforcement of cotton fabric. A cup used on the single-acting operating cylinders of railroad air brakes is shown in Fig. 19-20; similar cups are used on the double-acting cylinders employed to operate the locomotive reverse gear. All cups are self-tightening in that the full fluid pressure within the cup opposes the reduced pressure of the escaping fluid along the working face. To make this effective, it is necessary that contact with the cylinder wall be principally at the lip and that the heel be held slightly away. Also, air cups are effective only when supplied with an oil film, which must be renewed at intervals.

Reciprocating-pump pistons for water or aqueous solutions are usually packed with a hard variety of duck-rubber packing known as "hydraulic." Hardness is secured, in part, by substituting fine fabrics (sheetings or drills) for duck. It is supplied in the form of rings cut from bias strip with a step joint (Fig. 19-34*b*) or prepared from such strip in the field. Rings are used singly in grooves (Fig. 19-34*a*) or in sets with the joints staggered. Rings of hard rubber (ebonite) are used for the same service. Many water pumps, including the familiar farmhouse well pump, are packed with leather or duck-rubber cups. Mud pumps used in rotary drilling represent a severe piston-packing service—they are packed with massive rubber cups reinforced with fabric or metal or with V rings (Fig. 19-34*d*). Oil- and solvent-pump pistons are also packed with cups or with rings cut from laminated phenolic resin.

Liquid piston motors are generally of the oil-operated type. The pistons are packed with V rings or O rings. Rubber cups are employed, however, on the automobile hydraulic brake, the fluid in this instance being an alcohol mixture which has no appreciable swelling action on rubber.

Piston valves are packed in the same manner as the pistons of engines, air motors, or liquid motors, with the added complication that the packing is required to pass ports and must therefore be of fairly rigid construction.

Commonly used piston packings are classified in Table 19-8. A list of recommendations for utilities and general services is given in Table 19-9 and for chemical services in Tables 19-7 and 19-10.

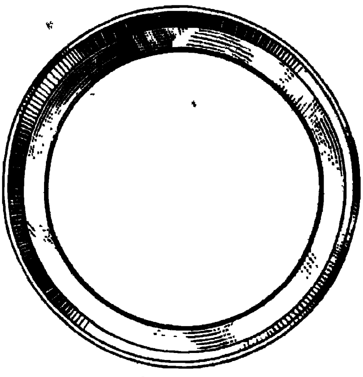

FIG. 19-20. Railroad air-brake cup.

ROTARY SHAFT PACKINGS

Rotary shaft service is generally more severe than reciprocating in that surface speeds are high, and facilities for dissipating frictional heat are poor. Solid duck-rubber packings, V packings, etc., such as are commonly used on reciprocating service, are not suitable on rotary service for any but the slowest speeds, since they will heat up and seize. Service is limited to types which are either inherently low in friction or which contain voids or a fusible binder which will act as a safety valve against thermal expansion.

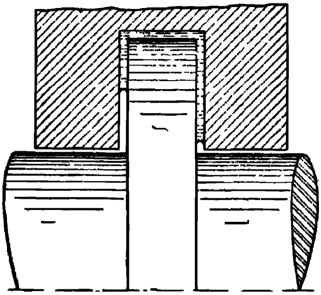

FIG. 19-21. Water seal.

Steam-turbine packings are of three types, none of which is employed to any extent for other rotary applications. The carbon-ring packing is similar to the segmental metal type except that it is made of graphite; it is installed in an oversize groove. It depends for its effectiveness on the seal formed by condensate. The water seal (Fig. 19-21) is scarcely a packing at all; it employs coarse clearances and depends on the principle of the U tube; the normal gravitation head of the water in the seal is intensified by the high rotational speed. Means must be provided to replenish the water in the seal if condensation is not sufficient. Similar liquid seals employing mercury are used on vertical centrifugal pumps. The labyrinth packing (Fig. 19-22) is employed on the larger turbines. It likewise employs coarse clearances, but the escape of steam is retarded by the length of escape path, which includes a miniature vortex within each annular pocket. Condensate is not necessary for the effectiveness of a labyrinth packing.

The centrifugal pump represents probably the largest single use for rotary packings. Speeds are high, but pressures opposite the packing are usually low, approximating that of the pump inlet. Nevertheless, to get any length of life from conventional packing necessitates a leakage tolerance on the order of 1 cc per min per circumferential inch of shaft when handling water. Pumps operating under higher pressures, such as those used as booster pumps on closed systems or multistage pumps, necessitate even higher leakage tolerances unless the pressure can be partly bled away by a lantern ring at the bottom of the box connected to a point of lower pressure. Some pumps are equipped with internal "pump-out" arrangements which make it possible to dispense entirely with packing except when the pump is idle. With more viscous liquids such as oil, somewhat lower leakage rates can be maintained, and the necessity for special arrangement is correspondingly lessened.

Since a centrifugal packing makes no pretense of being fluid-tight, sealing is indicated for all vacuum applications and for all positive pressure applications involving suspensions, concentrated solutions, or fluids that are extremely volatile, noxious, or valuable. For concentrated aqueous solutions with conventional packings, the usual sealing fluid is cold water from an independent source. Oil-refinery pumps handling solvents of low viscosity or high volatility are usually sealed with lube oil.

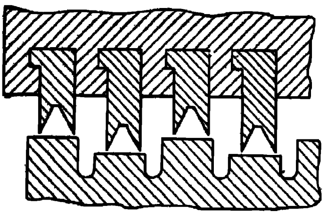

Fig. 19-22. Labyrinth packing.

Packing types employed with centrifugal pumps include "plastic," metal foil, braided, and axial seals. The first three are used in conventional stuffing boxes and require no special description. Axial seals are increasing in popularity and, in many cases, result in superior performance.

An axial seal consists essentially of a rotating ring or shoulder attached to the shaft making contact on one of its flat faces with a stationary ring attached to, or integral with, the pump housing. The patent literature on axial seals embraces several thousand designs, and new ones are being patented continually. These, however, may be reduced to a relatively few categories. A primary division is between single seals and those involving two seals in tandem ("double" seals). A second basis of classification for single seals is between those (designated "inside") in which the fluid pressure acts to tighten the seal (Figs. 19-33*a*, *b*, *g*, *h*, *i*) and those (designated "outside") (Figs. 19-33*c*, *d*) in which the pressure tries to blow the seal apart. Double seals always include one "inside" and one "outside" seal and may be differentiated as "expanding" (Fig. 19-33*e*) and "contracting" (Fig. 19-33*f*). Since all seals involve one flexibly suspended member, a third division is between those (which may be called "regular") in which the flexibly suspended member is stationary (Figs. 19-33*a*, *c*, *g*, *h*) and those (which may be called "inverted") in which the flexibly suspended member rotates with the shaft (Figs. 19-33*b*, *d*, *i*). A fourth basis of classification is the type of flexible suspension employed, *viz.*, sliding contact, flat diaphragm, and cylindrical diaphragm (or "bellows"). These are illustrated, for inside regular designs only, in Figs. 19-33*a*, *g*, and *h*, respectively.

The advantages and disadvantages of these various constructions are for the most part based on relative cheapness of design, accessibility, etc., and all types are capable of giving good service when operating against pure liquids such as water or oil. When operating against gases or against pure liquids containing dissolved or suspended matter, it is necessary that they be sealed just as any other packing. This may be done by injecting lube oil or grease directly into the sealing face or, in the case of a double seal, into the space between the two seals at a pressure higher than that of the fluid being packed. Selection of materials for seal rings, suspension member, and spring is governed by service conditions and should be referred to the seal manufacturer. Axial seals do not eliminate leakage, although they reduce it to a very low value—on the order of $^1/_{100}$ cc per min. As compared to other packing types, they are expensive, difficult to repair or replace, and if incorrectly selected for the application, may fail as quickly as, or quicker than, conventional types. Their use on centrifugal pumps is increasing.

Rotary displacement pumps and turbopumps are packed the same as centrifugal pumps. Surface speeds are generally lower, but pressures opposite the packing are generally higher, since the shaft in these pumps represents a point midway in the leakage path across the face of the rotor and therefore is at a pressure midway between inlet and discharge. In screw pumps, full discharge pressure comes opposite one packing. These pressures can be avoided, however, by tapping the bottom of the stuffing box directly to the inlet side at a minor sacrifice of pump efficiency.

Rotary gas compressors range from simple fans to pressure blowers of the Roots-Connersville type. Sealing liquid is indicated unless already present in the compressor body, as in the case of the Nash compressor. The type of packing is governed by the sealing fluid employed.

Agitators are packed the same as centrifugal pumps except that, on the slower moving shafts, it is sometimes possible to use duck-rubber V rings. Packings operating against gases, which applies to practically all chemical reactors in which the agitator enters at the top, should be sealed with some fluid that is compatible with the material in the reactor. Sometimes one of the reactants is employed for sealing purposes.

A list of recommendations for centrifugal pumps, displacement pumps, rotary gas compressors, or agitator shafts against fluids is given in Tables 19-6 and 19-7.

Fluid drives, fluid brakes, and rotary shock absorbers are similar to displacement or turbopumps and are packed in the same manner.

Swivel joints are required to handle all kinds of fluids at slow speeds; packings are generally cups or V rings. Two important swivel-joint applications are (1) steam connections for railway cars and (2) drilling mud connection to rotary rock drill. Ball joints used as swivels are described under Miscellaneous Sliding-contact Packings.

Hydraulic Turbines and Propeller Shafts. Packings for shafts of hydraulic turbines and for propeller shafts of vessels are analogous to centrifugal-pump packings and are packed in the same way. Braided flax seems to be preferred for these with, occasionally, rubber end rings to filter out suspended sand. Better results on dirty water are secured by sealing with clean water. This is often done with water wheels but less often with propeller shafts. Either application is operated on a continuous water leak.

An important application for rotary shaft packing is the crankcase of the *reciprocating* internal-combustion engine. There is little pressure but a great deal of surface speed, shaft gyration, and heat. This is an important application for the radial seal (Fig. 19-32) which consists essentially of a synthetic-rubber flange packing and a spring, the whole being usually encased in a stamped-metal shell which merely needs to be pressed into or bolted to the cavity surrounding the shaft. Springs are of the lug or garter type. Sometimes the shell reduces to a reinforcing member within the element, and the spring is omitted. Unfortunately, many internal-combustion engines, including the rear end of the crankcase on the ordinary automobile engine, are so designed that any seal employed must be split for installation. As a result the radial seal has not heretofore been able to displace conventional packings for this application, the latter consisting usually of half circles of cork, felt, or braid installed in grooves. Split radial seals, however, have become recently available. Radial seals are regularly employed on shafts leading to generators, distributors, and other accessories. There are a great many such seals on the modern aircraft engine. The piston ring seal (Fig. 19-31*a*) is used for somewhat similar purposes.

Single-acting reciprocating air compressors employ crankcase seals similar to those used on engines. Single-acting refrigerating compressors, however, usually operate with a pressure in the crankcase, which rises to the vapor pressure of the refrigerant at shutdown times. Radial seals are not well designed to pack against pressure, and resort is had to conventional packings or to axial seals. Conventional packings used for refrigerant service are largely duck-rubber slab or metal foil, packing being sealed by lube oil from the compressor lubricating system. Where the refrigerant has a swelling action on the rubber, as for instance, Freon or methyl chloride, packings with solvent-resistant binders must be employed. Success with conventional packings on refrigerant compressors is largely a matter of care in wearing in. Axial seals are expensive and difficult to replace but when properly designed are satisfactory and require no attention. Axial seals of the metal-bellows suspension type were widely employed on domestic refrigerating machines until the advent of the hermetically sealed unit, which requires no packing.

Bearings and Gear Cases. The most conspicuous expansion of the radial seal has been in the general field of bearings and gear cases. Until comparatively recently, such apparatus was either allowed to leak oil freely or was lubricated with semisolid grease. The automobile manufacturer, because of the need of protecting his expensive ball and roller bearings, inaugurated the first widespread use of radial seals. Many such seals are now incorporated integrally with the ball bearings; since the bearing in such cases is supplied with grease, the function of the radial seal appears to be principally that of excluding dirt and water. Many such seals, however, are employed against liquid lubricants and serve to cut losses to a minimum. Instances are electric-motor bearings, pillow-block bearings, all kinds of reduction gearing, belt pulleys, chain sprockets, conveyor rollers, rollers for dam gates, etc. Very large radial seals are employed on steel-mill roll necks and on the gun platforms of warships. Work is under way that will probably lead to the use of radial seals for railway-car journals.

VALVE-STEM AND EXPANSION-JOINT PACKINGS

Valve-stem-packing service is distinguished from preceding types of sliding-contact service by slight and infrequent movement, continuous high pressure, and little or no attention. Regarding the latter, many valves are in inaccessible locations where packing adjustments can be made only with great difficulty.

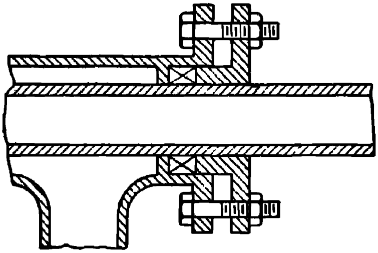

FIG. 19-23. Expansion joint - double-tube heat exchanger.

Direction of motion in valve-stem packing can be reciprocating, rotary, or a combination of both, *viz.*, helical. Which direction is not of great importance because of the low speed involved. Packings may be of the reciprocating types, *viz.*, fabric–rubber-slab or rolled constructions; V rings, cones, O rings, etc., or they may be of the rotary types, *viz.*, braids, plastics, or metal foil. The real problem is one of fluid sealing, since valve users will seldom go to as much trouble to seal valve-stem stuffing boxes as they will to seal pump stuffing boxes. The same necessity for sealing, however, exists when dealing with gases, vacuum, or liquids that are of low viscosity, volatile, corrosive, poisonous, or full of dissolved or suspended matter. The following sealing means, both more or less makeshift, are employed:

1. Valves carrying condensible gases, such as steam, are provided with extension bonnets with cooling fins to promote condensation, the liquid providing the necessary sealing. Inverting the valve is also helpful.
2. Stuffing boxes, if accessible, are provided with lantern rings and alemite or other grease connection for intermittent grease injection. This arrangement excludes the fluid from the packing for only a brief period, in addition to which it is frequently neglected. In lubricated plug cocks, the fluid injected to lubricate the plug serves also to seal the stem packing.

Most of the troubles associated with valve-stem packings would be avoided if manufacturers would provide sealing connections and if users would couple these to a central source of lube oil at a pressure greater than that of any of the fluid lines or else provide each valve with a properly designed spring-loaded grease cup. Some such device is especially needed with control valves to minimize hysteresis resulting from valve-stem-packing friction. Such arrangements are for fluids other than pure water or oil, these causing no particular trouble if a slight leak is permitted.

Certain valves impose special requirements on the stem packing. In some conical plug cocks, the stem packing is required to hold the plug in place; this necessitates a somewhat denser construction than usual. In a plumbing faucet, the stem packing is driven flush into the stuffing box by the act of tightening the bonnet and is not thereafter adjustable. This necessitates a packing that is closely controlled for volume, does not lose volume rapidly in service, and has voids to absorb thermal volume changes. The duck-rubber-slab packing meets these requirements.

Reciprocating expansion joints, although larger than valve stems, are similar in respect to service requirements, since movement is slow and infrequent and also since they are required to handle a wide variety of fluids. In addition to their use in pipe lines, they are employed in heat-exchanger equipment of the double-tube (Fig. 19-23) and shell-and-tube (Fig. 19-24) types.

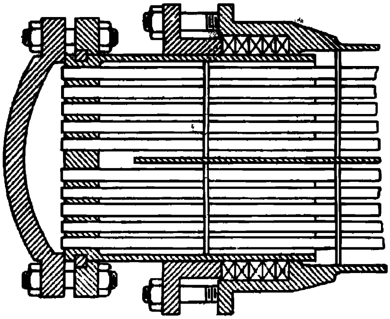

FIG. 19-24. Expansion joint—shell-and-tube heat exchanger.

Recommendations for valve-stem and expansion-joint packings for various services are given in Tables 19-6 and 19-7.

MISCELLANEOUS SLIDING-CONTACT PACKINGS

The preceding material has dealt with packing the interface between concentric cylindrical members. Sliding-contact packings are also used to pack flat, conical, and spherical interfaces.

Axial seals represent a type of flat-surface packing, although used in lieu of a conventional cylindrical-surface packing. More typical flat packings are those used with ported valves. As far as is known, the familiar steam-engine D slide valve depends entirely on metal-to-metal fit, but somewhat similar three- and four-way valves used for air, water, or oil are sometimes packed along the flat interfaces. Relatively hard packings, such as laminated phenolic resins, are used to avoid damage to the packing in passing ports.

The only well-known application of a packing for a conical surface is the so-called "lined" plug cock. The lining, which is really a packing, is required to pass ports as the plug rotates. It therefore must be made of firm material. A molded asbestos-ebonite composition is favored.

Spherical packings for ball joints are widely used. Ball joints are located in pipes to permit rocking or a combination of rotation and rocking. One of the former type is the Mallet engine joint shown in Fig 19-25. In addition to packing the ball against steam leakage, the packing in this case is also required to support the ball thrust and therefore must be made of firm material. A folded asbestos-fabric-rubber construction is currently employed.

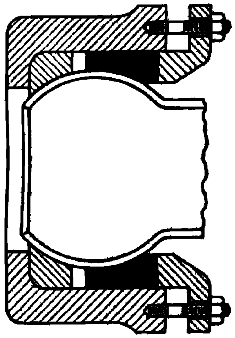

FIG. 19-25. Mallet ball joint.

GASKET AND SLIDING-CONTACT-PACKING CLASSIFICATION AND RECOMMENDATIONS

Author's Note. The gasket and rod-packing recommendations given in this section represent merely the most widely used industrial practice. They do not pretend to be exhaustive and undoubtedly there are instances under the various service classifications wherein types of packing not indicated may be giving service equal to or better than the types shown.

HOW TO SELECT PROPER PACKING

Classification of mechanical packings and recommendations for specific services have been summarized in Tables 19-2 through 19-10. To select the proper packing or gasket for a specific service, refer to the appropriate table to find the type or types recommended. Then turn to the preceding classification table to interpret the recommendation.

EXAMPLE: To find recommended gasket for standard pipe flanges in ammonia gas service, see Table 19-3, in which gasket recommendations for utilities and general services are presented. For ammonia gas at temperatures up to 220°F, style 211 gaskets are recommended. Now referring back to Table 19-2, in which flange gaskets are classified, it will be noted that style 211 gaskets are of the compressed asbestos type (2, first column), made from white asbestos fibers (1, second column), and bonded with natural rubber or GR-S (1, third column).

Table 19-2. Classification of Flange Gaskets

Nonmetallic gaskets

General type	Materials		Forms available
	Reinforcement	Binder	
1. Plain rubber or other polymer	0. None	1. Natural rubber or GR-S 2. Neoprene 3. Buna N 4. Butyl 5. Thiokol 6. Teflon 7. Polyvinyl chloride (Koroseal, Tygon, etc.) 8. Silicone rubber	Sheet and gaskets cut from sheet Strip and gaskets spliced from strip Sleeves and gaskets cut from sleeves Molded shapes
2. Compressed asbestos	1. White asbestos 2. Blue asbestos	1. Natural rubber or GR-S 2. Neoprene 3. Buna N 4. Butyl	Sheets and gaskets cut from sheet
3. Leather	1. Combination tannage leather 2. Chrome-tanned leather	5. Thiokol 8. Wax 9. Phenolic resin	Hides and gaskets cut from hides
4. Braid	1. Flax or jute 2. White asbestos with copper or brass wire 3. Blue asbestos	0. None 1. Natural rubber or GR-S 8. Silicone rubber	Eight-carrier braid Multiple-carrier braid (solid) Multiple-carrier braid (hollow) Interlocking
5. Fabric	1. Cotton fabric ("CI sheet") 2 White-asbestos fabric 3. White-asbestos fabric with copper or brass wire 4. Blue asbestos	0. None 1. Natural rubber or GR-S 2. Neoprene 8. Silcone rubber	Sheets and gaskets cut from sheet Strip and gaskets spliced from strip Gaskets rolled or folded from endless sleeves

DIAPHRAGMS

A packing diaphragm spans a gap between a moving and a stationary member, permitting limited motion in the former. It makes a fluid-tight contact with both members, with or without supplementary gaskets.

Since a diaphragm functions in the same manner, except for absence of leakage, as a sliding-contact packing, there are diaphragm equivalents for all the various types of sliding-contact packings. The diaphragm in the air motor (Fig. 19-35) may be looked upon as the equivalent of a reciprocating piston packing. Such motors are used to operate valves, switches, or perform any other simple mechanical act such as to apply brakes, press garments, or operate a recording instrument. Fluid pressure, in the case of a motor valve, may be derived from the fluid in the line or from air or other fluid supplied by a pilot valve which is itself operated by the fluid in the line or otherwise. If the

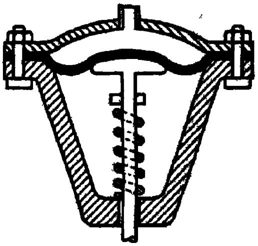

Fig. 19-35. Air-motor diaphragm.

fluid is too destructive to the diaphragm material, a suitable siphon of harmless fluid may be interposed. Thus, in the case of steam-operated diaphragm motors, direct contact of the diaphragm with steam is avoided by having a loop in the connecting pipe which fills with condensate.

A list of diaphragm packings is given in Table 19-11.

Table 19-11. Classification of Diaphragm Packings

Type	Materials		Physical shape or method of fabricating
	Reinforcement	Binder	
1. Plain	0. None	1. Natural rubber (or GR-S) 2. Neoprene 3. Buna N	1. Sheet (or diaphragms cut from sheet) 2. Molded with dished or troughed contour 3. Molded with cylindrical corrugations (bellows)
2. Fabric	1. Cotton 2. Nylon 3. Glass	1. Natural rubber 2. Neoprene 3. Buna N 4. Silicone rubber	1. Sheet (or diaphragms cut from sheet) 2. Molded with dished or troughed contour
3. Metal	1. Carbon steel 2. Stainless 3. Bronze 4. Aluminum	0. None	1. Sheet (or diaphragms cut from sheet) 2. Flat corrugated 3. Cylindrical corrugated (bellows)
4. Leather	1. Sheepskin	1. Animal or vegetable oil	1. Hides (or diaphragms cut from hides) 2. Molded with dished or troughed contour

Sheet-metal diaphragms are used for diaphragm motors at high pressures. Flat corrugated metal is used principally for aneroid barometers and thermostats. Metal bellows (Fig. 19-36) are widely used in refrigerator control valves. They are available in a limited number of sizes and need to be gasketed or soldered to adjacent parts. They have the advantage of long travel, which, however, must not exceed the elastic limit of the metal, or early failure will occur by fatigue. Flat leather diaphragms are largely used in gas meters and regulators because of their resistance to benzol. Flat fabric–rubber diaphragms are used for general service. A few precautions to be observed in their use are shown in Fig. 19-37. Flat fabric diaphragms are capable of only about 2 in. travel per ft of diameter (1 in. either side of the plane of the rim), and in an effort to increase this, diaphragms are sometimes bought premolded to various contours of which the simple dished contour (Fig. 19-38) is the best. The advantages of molded diaphragms over flat diaphragms in respect to travel is very slight, however, and is frequently lost because of concealed damage to the fabric in the molding operation. Plain rubber is used when pressure differentials are very low.

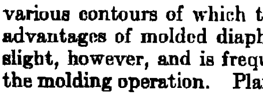

Fig. 19-36. Metal bellows.

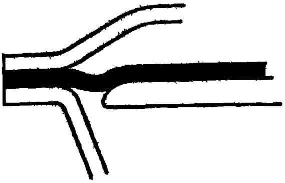
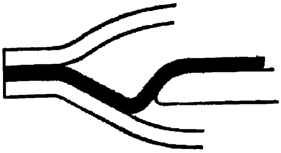
The cover compound on most fabric diaphragms is based on natural rubber or GR-S, but oil resistant synthetics are used for services against oil or against air containing oil, as in "garage-type" air-compressor switch motors or in the unloading mechanism of large air compressors. Covers of oxidized oil (oilcloth), nitrocellulose, etc., were used at one time for solvent service but have been largely displaced by the synthetic rubbers. Covers of silicone rubber are of interest where extremely hot air is involved.

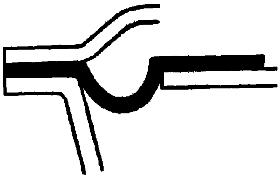
Corresponding to the piston pump is the diaphragm pump. Pump diaphragms are usually special because of the severe service and possibility of early fatigue failure. Small diaphragm pumps are used to pump fuel to the automobile engine (Fig. 19-39). A variant is the liquid-piston diaphragm pump (Fig. 19-40) in which the diaphragm serves merely as a separator and is under no stress. Plain rubber, therefore, can be used. Similar diaphragm separators are employed with air accumulators on oildraulic systems which function alternately as pumps and as motors. There are also



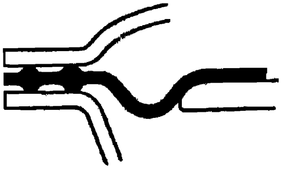
Don't make free space narrow



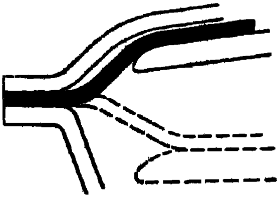
Don't make case too shallow



Don't leave sharp angles



Don't use beaded rims
(or beaded flanges)



Don't use all the slack

IG. 19-37. Precautions in the se of diaphragms.

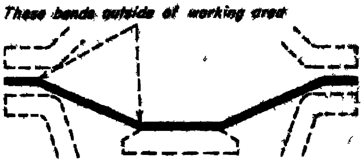


FIG. 19-38. Molded diaphragm.

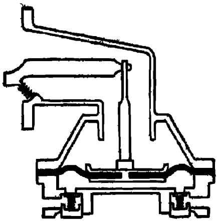

FIG. 19-39 Diaphragm pump (automobile)

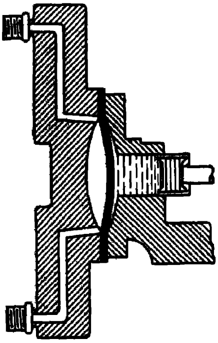

FIG. 19-40. Liquid-piston diaphragm pump.

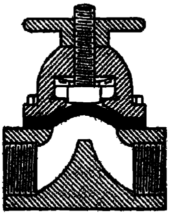

FIG. 19-41. Saunders valve.

diaphragms used as air-compressor pistons on portable spray outfits. This service is severe not only because of the speed of operation but also because of oxidation.

Diaphragms are also used as valve-stem packings, usually in the form of bellows, as in the so-called "packless" radiator valves. In the Saunders valve (Fig. 19-41), the diaphragm functions simultaneously as a valve-stem packing and as a valve disk. Diaphragms of many different materials are available to combat various fluids.

Axial seals employing diaphragm suspensions, both flat and cylindrical, have been mentioned under Rotary Shaft Packings. The domestic refrigerating-machine crankcase seal was, until recently, the principal market for the metal bellows. Some of the bellows used on water-pump seals, as in the familiar automobile-radiator pump, are of plain rubber, the pressures being insufficient to necessitate any reinforcement.

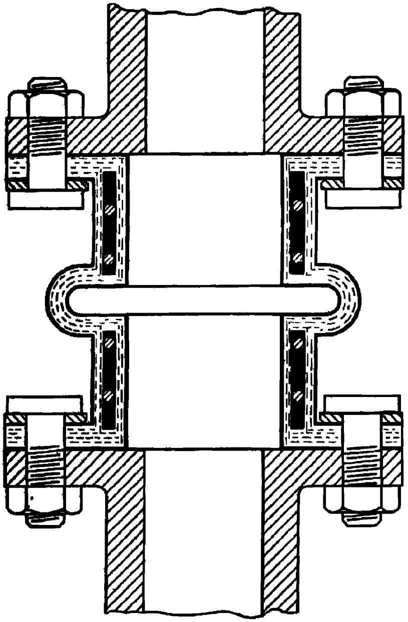

FIG. 19-42. Bellows expansion joint.

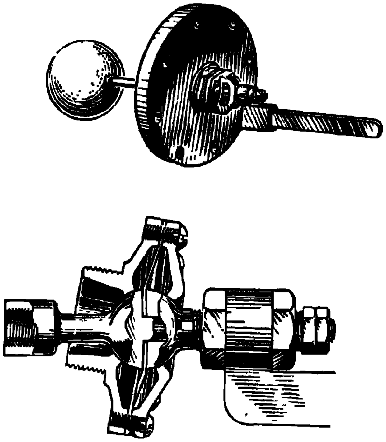

FIG. 19-43. Diaphragm-packed float valve.

Other uses for packing diaphragms are (1) the bellows expansion joint (Fig. 19-42), replacing the usual sliding-contact type, and (2) the diaphragm-packed float valve (Fig. 19-43). These permit rocking around an axis in addition to straight push and pull. The familiar Bourdon tube may be looked upon as a motor diaphragm adapted to produce rotary motion. Bellows with helical corrugations have been employed for the same purpose.

PACKING TESTING AND EVALUATION

Packing tests include field tests, bench tests, and laboratory tests.

Field Tests. In the last analysis, there is no satisfactory way to evaluate a packing except to observe its performance under service conditions. The packing bill of any large process industry is sufficient to warrant employing an engineer with nothing to do but to supervise packing performance. Such an individual should have at his disposal a card index with a card for each important packing application, covering complete dimensional data, operating conditions, and a record of the life of each successive packing installed. An attempt should be made to determine the causes of packing failure by examination of removed material and by periodic examination of shafts, cylinder liners, etc., for scoring, excessive clearances, misalignment, and weave or gyration. Although such supervision is installed primarily to differentiate between packings of various suppliers, its greatest benefit consists in the prolonged life conferred on all packings by closer attention to the mechanical condition of equipment, to the installation of seals and other desirable accessories, and to instruction of the operating force. In smaller organizations the functions of packing engineer, lubricating engineer, and power-transmission engineer are frequently combined.

Packings for original equipment are tested as part of the "green run" to which the equipment is subjected on the assembly floor of the supplier's plant. Unfortunately these "green runs" are frequently of too short duration to tell much about

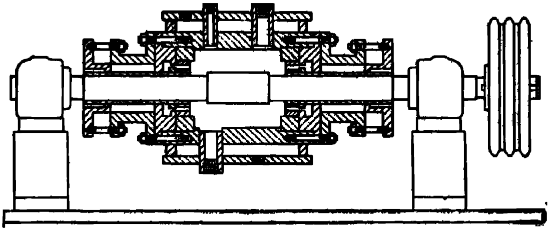

Fig. 19-44. Cross section of two-cavity bench tester.

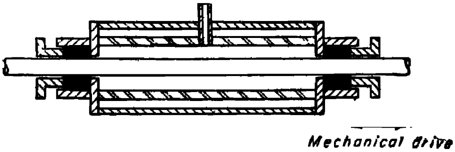

Fig. 19-45. Balanced-type tester (one type).

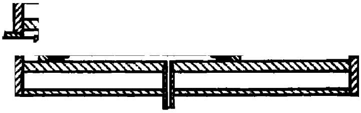

Fig. 19-46. Balanced-type tester (another type).

packing performance, especially as most packings do not exhibit their best performance until after several hours or days of continuous running. Performance should therefore be checked by tests run to destruction on a small portion of the product.

Bench Tests. For those who have the time and money to spend in accurate packing evaluation, satisfactory results free from personal error can be secured on laboratory bench machines set up to duplicate service. Figure 19-44 shows a cross section of a two-cavity bench tester suitable for all types of rotary shaft packings. Any medium at any pressure and temperature can be introduced into the interior, any speed of drive can be employed, and any degree of shaft runout can be induced by wear sleeves of predetermined eccentricity. Leakage is collected and measured, and packing adjustments as necessary are made to maintain a predetermined leakage rate. Stuffing boxes can be modified to permit tests on radial or axial seals. In Figs. 19-45 and 19-46 are shown "balanced-type" testers suitable for testing reciprocating rod packings and piston packings, respectively. In Fig. 19-47 is shown a device for continuously opening and closing valves—it can be employed to test valve-stem packings or valve disks. In Fig. 19-48 is shown a device for flexing diaphragms

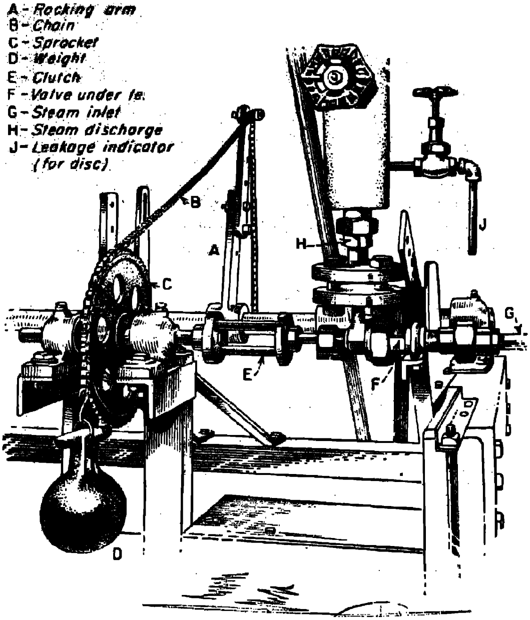

FIG. 19-47. Device for continuously opening and closing valves.

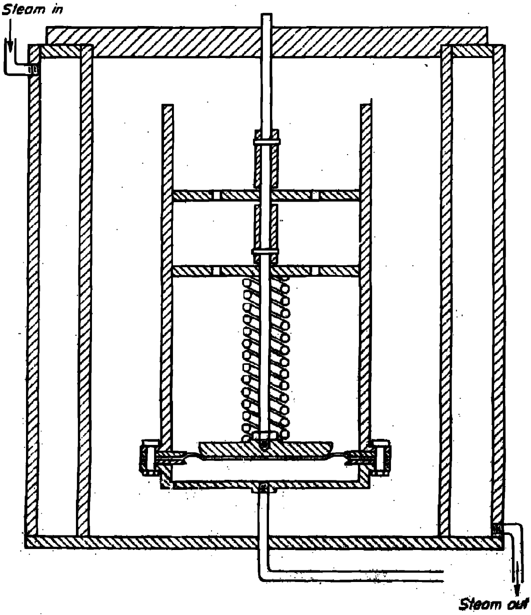

FIG. 19-48. Device for flexing diaphragms to destruction.

to destruction. The device is so constructed that the diameters of piston and cylinder, the radii of the corners, the stroke, the nature and pressure of the actuating medium, and the ambient temperature can all be modified at will. All these dynamic testers can be made to indicate packing friction or record it continuously. In Fig. 19-49 is

shown a flange tester for gaskets, and in Fig. 19-50 it is shown installed in a heavy-duty test machine. This device can be used to record gasket compression, creep, and relaxation under practically all conditions of fluid medium, pressure, temperature, and condition of flange surfaces. In addition to their value for evaluating competitive packings, machines such as above described are invaluable as research tools for exploring the effect of varying operating conditions on packing performance.

Laboratory Tests. Laboratory tests for plain rubber packing include the following:

Tensile and Elongation Tests. Tensile and elongation tests are conducted on dumbbell strips on a test machine of the type shown in Fig. 19-51. Details for conducting the test are given in ASTM-D-412. Where the dimensions of the packing do not permit cutting the standard test specimen, approximate value can be obtained from nonstandard specimens. For instance, O rings can be tested over spool jaws.

Set Tests. Set tests include tension-set and compression-set determinations. Both involve the exposure of a strained specimen to a predetermined temperature for a fixed time and the measurement of the resultant recovery. Tension-set tests are conducted on dumbbell (or equivalent) specimens in accordance with ASTM-D-412. Compression-set tests are conducted on cylindrical specimens which in certain cases may be plied up from thinner material. Method is given in ASTM-D-395.

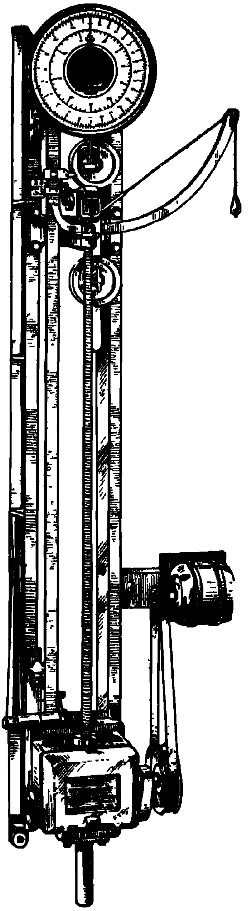

FIG. 19-51. Tensile and elongation test machine.

Hardness Tests. Hardness tests involve measurement of the penetration of a point of fixed dimensions under a predetermined load. Spring-loaded portable instruments are generally known as "durometers" and record penetration on an inverted scale, ranging from 100 for a rigid object down to about 20 for a very soft rubber. Method for calibrating and using these is given in ASTM-D-676. The ASTM penetration tester (sometimes known as the Olsen tester) and the plastometer (Pusey & Jones) are bench machines employing dead-weight loading. They are less convenient than the durometers but more accurate in that they do not require calibration. Standard methods for employing these are given in ASTM-D-314 and D-513, respectively.

Hot-air Aging Tests. Hot-air aging tests involve exposure of a tensile or hardness specimen to circulating hot air, the effect being measured by resultant changes in tensile, elongation, or hardness. Methods are given in ASTM-D-573. Closely related are the oxygen-bomb and air-bomb aging tests which are described in ASTM-D-572 and D-454.

Solvent or Oil-immersion Tests. Solvent or oil-immersion tests involve immersion of the test specimen in a specified solvent or in lubricating oil for a predetermined time and temperature and measuring the resultant changes in volume, tensile strength, elongation, or hardness. Methods are given in ASTM-D-471.

Modification of above tests applicable to compressed asbestos sheet are given in ASTM-D-733. Packings constructed from plied-up fabric can be tested for ply adhesion in accordance with ASTM-D-413. Standard methods are also available for testing paper, leather, yarn, metals, etc. In addition, any of the recognized chemical methods for the separation and identification of ingredients may be applied to packings of any type.

A point to be observed in connection with all laboratory tests is that they do not by themselves supply a measure of packing serviceability. They are employed legitimately as a means of demonstrating the uniformity of successive shipments of a packing which has been originally approved on the basis of field or bench tests.

INTRODUCTION

The handling of materials, either in their raw state or as semifinished or finished products, is a large and important problem in modern industry. Efficient handling of materials is the cornerstone in the layout of plants in the mass-production industries. Within a plant the movements of material should be as few and as short as conditions will permit. Some layouts lend themselves to the use of gravity for moving the materials, decreasing the amount of machinery required.

There are many different devices for elevating and conveying materials. Solving a particular problem requires the selection of a device that experience has shown to be suitable and one whose initial and maintenance costs are consistent with the amount of work done.

BULK MATERIALS

There are many difficulties which arise in the handling of bulk materials which are not present in the conveying of units, pallets, or packaged goods. Study should be given to the following factors: possible degradation of the material, discoloration and impurities, abrasive effects, and dust produced with respect to its injurious effects on workers and the possibility of explosion and fire.

The handling of bulk materials has been divided into two parts: unloading and conveyance. For a brief comparison of the types of elevators, see Table 20-1, and of conveyors, see Table 20-2.

Table 20-1. Bucket Elevators

	Centrifugal discharge	Perfect discharge	Continuou bucket	Gravity discharge	Pivoted bucket
Carrying paths	Vertical	Vertical to inclination 15 deg from vertical	Vertical to inclination 15 deg from vertical	Vertical and horizontal	Vertical and horizontal
Capacity range, tons per hr, material weighing 50 lb per cu ft	78	34	345	191	255
Speed range, fpm	306	120	100	100	80
Location of loading point	Boot	Boot	Boot	On lower horizontal run	On lower horizontal run
Location of discharge point	Over head wheel	Over head wheel	Over head wheel	On horizontal run	On horizontal run
Handling abrasive materials	Not preferred	Not preferred	Recommended	Not recommended	Recommended

Handling abrasive materials	Recommended	Recommended	Not recommended	Recommended with special steels	Not recommended	Not preferred	Recommended

UNLOADING

Railroad-car Unloaders

Track Hoppers. Track hoppers are used principally for materials shipped in bottom-dump cars, where requirements are not over 2 to 2½ tons per min of material weighing 50 lb per cu ft. The concrete foundation may be shaped to form the hopper, or separate steel hoppers may be installed below the track level. For effective dumping with a minimum of spill, it is recommended that the hopper be not less than 12 ft wide. A hopper 12 ft long will accommodate a 50-ton two-door car; while for a 70-ton four-door car (and for more effective discharge of a 50-ton car), the track hopper should be 22 ft long. To reduce depth of pit required and the cost involved for a 22-ft-long track hopper, it generally is better to use two 12- by 12-ft units placed end to end.

The speed of discharge of a car will vary greatly with the condition of the material at the time the car is unloaded. Fines mixed in with the load will often pack down during transit requiring the load to be loosened by barring or by striking the side of the car to vibrate the load loose. Packed and partially frozen material can easily be removed by means of mechanical shaker units. Where the load is wet or frozen, the time of unloading may be as much as doubled, even with additional laborers on the job. Mechanical devices such as traveling augers, shakers, and air-hammer spuds may be used to accelerate the dropping of frozen material. Under good conditions a car may be unloaded in 10 to 30 min, depending upon the size of car, size of hopper, characteristics of the material, and number of laborers assisting the operation.

Cars may be spotted over the hopper by an industrial locomotive of the diesel, steam, fireless-steam, compressed-air, or electric type or by a capstan car puller. The car puller is ideal for intermittent operation since the electric-motor drive need be operated only while the car is being spotted. Car movement is facilitated if the track is on a slight downgrade.

The capacity of the elevator away from the track hopper should be great enough to provide sufficient room in the hopper for the dumping of the succeeding car, but not so large that the elevator will run empty an appreciable portion of the time.

Crane Unloaders. A crawler, locomotive, or truck crane, available from other duties, is sometimes used with a clamshell or orange-peel bucket to unload gondolas. Flat-bottom cars should be available, for the bucket cannot readily unload hopper-bottom cars. A track hopper leading to a pit at the side of the track is used where the type of car cannot be controlled, and the crane may handle either from the car or from the pit.

Cranes are particularly adapted for temporary installations where unloading may be done into trucks, overhead bins, or storage piles. Some hand labor is required in the cleaning out of cars. Materials can also be received in bulk containers. In this case the units are usually removed by means of a monorail or bridge crane.

Rotary Car Dumpers. In cases where the required capacity is greater than that which can be handled with a track-hopper installation, a rotary car dumper (see Fig. 20-1) is used. While the initial cost is considerably greater than a track hopper, the operational cost per ton is low. Two or three unskilled laborers are all that is required, and the device is so simple that one of these laborers can handle the operational machinery.

The mechanism consists of two portal end rings with a cradle supported between them. The end rings are rotated on pairs of supporting wheels at each end of the dumper. Cable-operated clamps lock the car to the rails by pressure on the top of the car during the dumping operation.

The usual installation employs a switch engine to spot the cars on the dumper. Cars leaving the dumper are pushed onto an inclined track by the incoming car and are gravity-propelled to a storage yard. The capacity per hour will depend largely on the switching facilities available and may run as high as 30 cars an hour. A full dumping cycle takes approximately 1½ min. A frozen load will require slightly longer. These units cannot be used where material is received in a frozen state unless provisions are made for melting down the mass before dumping. The dumping time is not affected by sticking of the bottom gates. Units will handle cars of capacities up to 120 tons.

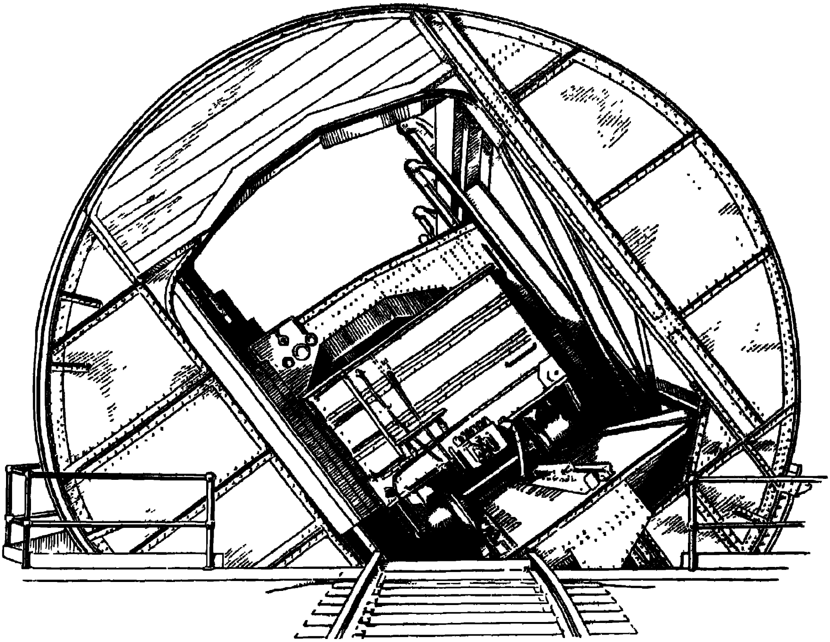

Fig. 20-1. Rotary car dumper.

Power Shovel. Where bulk material is to be unloaded from boxcars and the unloading-capacity requirements are moderate, a power shovel will efficiently perform the operation (see Fig. 20-2). The shovel is drawn into the car by the operator, whereupon a slight slackening of the rope from the shovel to the motor-operated drum serves to trip the mechanism engaging a clutch. The drum winds the cable pulling the shovel to the car door, at which point the clutch is automatically disengaged. At the door the material is discharged from the shovel into a hopper feeding the conveyors required to carry off the material.

From the description it can be seen that the power-shovel operation is fatiguing and hazardous. It, therefore, is suggested that a gasoline-powered scoop shovel be considered for these operations.

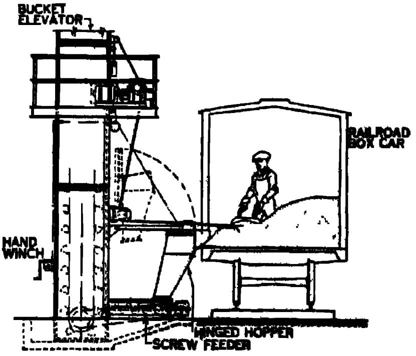

Fig. 20-2. Unloading box car by power shovel.

Pneumatic Unloaders. The pneumatic system, operating on the same principle as the vacuum cleaner, is particularly suitable for dusty materials deleterious to operators. The car-door bulkheads can remain in place, and the operator works from the outside except for final cleaning. A cyclone separates the material at the storage point, no elevators or conveyors being required, with the air usually discharged through a bag filter. Pneumatic units can be used efficiently with materials received in covered hopper cars with considerable savings in labor cost for unloading.

The unloading capacity will depend on the physical properties of the material in addition to the amount of air pumped and the difference in air pressure between the two ends of the system. The capacity will generally be greater than that of a power shovel, and the horsepower requirements will be higher. With high air pressures, abrasive materials may cause excessive wear at turns, and degradation of fragile materials may result. However, proper materials of construction, such as rubber lining or any of the many abrasion-resisting alloys, can solve these problems.

Packed or dense materials, such as cement, can be unloaded through the use of a Fuller-Kinyon pump. In the portable self-contained unit, a horizontal disk feeder delivers the material to a choke screw feeder in which it is aerated and fed into the conveying line, the air and material mixture flowing somewhat like a liquid.

Box-car Dumpers. For large capacities of grain or soybeans a box-car dumper is usually employed (see Fig. 20-3). It consists of a structural-steel cradle mounted on rollers at four points so as to permit endwise tipping in either direction to 40 deg from the horizontal and a car supporting platform pivotally mounted to permit sidewise tipping to an angle of 15 deg in one direction. The car is switched onto the supporting platform, then two end clamps engage the car couplers. The grain-door opening frame is brought into contact with the car door and locked against backward movement. The car is then tipped sidewise against the frame. This frees the car doors. The cradle is then tipped endwise, first in one direction, then in the other, removing the majority of the grain. A baffle plate is inserted diagonally across the car floor on the last endwise tip to remove the grain that might otherwise run past the door opening.

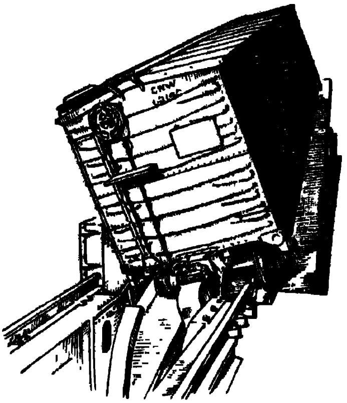

Fig. 20-3. Box-car dumper

The car platform returns the empty car to a horizontal position, the door opener is withdrawn, the end clamps are disengaged, and the platform is automatically locked. The empty car is then ready to be moved off the platform.

The time required for the complete cycle of operation is 4½ min. Under favorable conditions eight cars per hour can be unloaded with two men, or four cars per hour with one man.

Boat Unloaders

Installation of boat unloaders is very specialized, with each unit usually being designed for the particular job. Because the average plant does not receive bulk material direct from boats, only a brief mention of the types available is given.

Clamshell Buckets. For average capacity requirements or intermittent service, a clamshell bucket working from a monorail-system gantry crane or cantilever bridge with tramway hoist will prove satisfactory. The unit may discharge into cars along the wharf, into stockpile, or into a conveying system.

Hulett Unloader. The Hulett unloader consists of a gantry frame with a vertical leg having both vertical and rotating movements. A clamshell type of bucket operates at the lower end of this leg. The operator rides in the lower end of this leg where he is close to the work. Discharge from the bucket is into a hopper and weighing larry from where it may go into railroad cars or conveyor system. Capacities with a 17-cu-yd bucket are from 1,000 to 1,500 tons per hr of iron ore weighing 150 lb per cu ft.

Self-unloading Boats. With self-unloading boats, discharge from the boat to the wharf is over a belt conveyor mounted on a pivoted arm which may be swung to either side of the boat and raised or lowered. Cargo comes from the hold on a bucket elevator or belt conveyor which in turn is fed either by belt conveyors or by drag scrapers operating in tunnels at the bottom of the holds. Unloading capacities are in the range of from 1,000 to 2,000 tons per hr.

Pneumatic Unloaders. Grains are unloaded at the rate of 6,500 bu per hr by suction systems.

CONVEYANCE

Bulk Elevators

Skip Hoists. Skip hoists (Fig. 20-4) may, in general be classified into one of three types:

1. Single bucket without traveling counterweight
2. Single bucket with traveling counterweight
3. Two buckets operating reciprocally

The first type, in the simplest form, will consist of a rectangular bucket running on vertical or inclined tracks (or a combination of the two) with a hoisting cable and hoisting machine. Loading at the foot is usually from a hopper, but a conveyor intermittently operated is sometimes used. At the top of its travel, the bucket is usually tipped to discharge the material.

The use of a counterweight heavy enough to equal the dead weight of the bucket plus half that of the load will reduce the maximum motor load more than half, but the motor will be loaded in both directions of travel. A common method of connecting the counterweight is to have the counterweight cable wound on the same drum as the bucket cable but in the reverse direction.

In nonautomatic operation the stopping of the bucket at the top and bottom is controlled by the hoist operator. In the semiautomatic device the operator starts the hoist, which is automatically stopped at the top of the bucket travel, and after a time lag sufficient to allow the bucket to empty completely, the hoist is automatically reversed to return the skip to the starting position. It must now be restarted by the operator before another round trip is made.

In fully automatic operation, the skip continues to repeat its cycle until stopped by the operator. This requires some method of automatic loading, which may be one of four types:

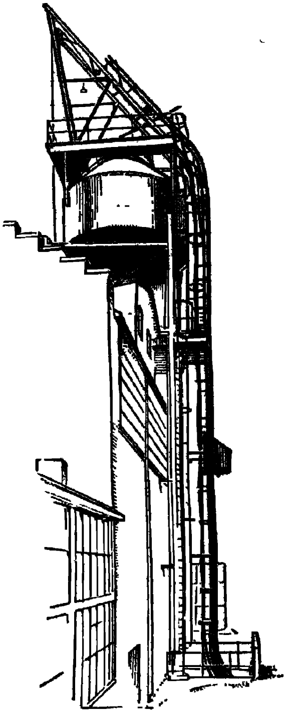

Fig. 20-4. Skip hoist.

1. The measuring type, in which the bucket is loaded with a predetermined volume of material before it recommences its upward trip
2. The weight type, in which the bucket is loaded with a predetermined weight of material before it starts its upward trip
3. The full-bucket type, in which the bucket will start upward only after it has been filled
4. The time-lag type, in which the bucket remains at the bottom a sufficient length of time to allow it to fill, overflowing of a bucket being prevented by the damming effect of the material as it reaches its angle of repose (this has the disadvantage that, if the hopper should empty or the spout jam, the bucket will continue to run whether it is loaded or not)

In the stock-piling of material a variation of the skip hoist is used in which the bucket, at the top of its travel on the rails, is lowered until it touches the top of the stock pile. This releases gates in the bottom of the bucket to dump the load, and there is no free fall of material with accompanying degradation.

The skip hoist may have a bucket capacity of 20 to 200 cu ft and will operate at a cable speed of 40 to 450 fpm. In addition to these factors, the tons of material handled per hour will depend upon the distance of lift and the weight per cubic foot of the material. Table 20-3 gives the capacities with fully automatic operation.

The skip hoist is dependable, easy to operate, has few moving parts, and for high lifts or large capacities, the first cost will be less than for any other type of mechanical conveyor. It is particularly adaptable for the handling of abrasive or corrosive materials or those which are either fine or lumpy.

Bucket Elevators. Under this heading the following types of bucket elevators are discussed: centrifugal discharge, perfect discharge, gravity discharge, continuous bucket, and the pivoted bucket carrier. For a brief comparison of these types see Table 20-1.

Table 20-3. Capacities of Skip Hoists—Automatic Loading, Fully Automatic Operation

Speed of bucket, fpm	Lift, ft	Tons per hr, material weighing 50 lb per cu ft					
		Bucket size, cu ft					
		40	60	80	100	150	200
80 (single speed, one bucket)	40	50	75	95	120	185	245
	60	35	50	65	80	125	165
	80	25	40	55	65	100	135
	100	22	30	45	55	85	110
	120	18	25	35	45	70	95
	160	14	21	30	35	55	70
	200	11	17	23	29	45	55
140 (single speed, one bucket)	40	70	105	140	175	265	350
	60	50	75	100	125	185	250
	80	40	65	85	105	155	210
	100	35	50	70	85	130	170
	120	30	45	60	75	110	150
	160	22	35	45	55	85	110
	200	18	27	35	45	65	90
260 (two speeds, one bucket)	80	60	90	120	150	225	300
	100	50	75	100	125	190	255
	120	45	65	90	110	165	225
	160	35	55	75	85	135	185
	200	30	45	60	75	115	155
260 (two speeds, two balanced buckets)	80	115	175	235	205	445	590
	100	100	155	205	255	380	510
	120	90	135	180	225	335	450
	160	75	110	145	170	275	370
	200	60	90	125	155	235	310

Centrifugal-discharge Type. The centrifugal-discharge type (Fig. 20-5*a*) of bucket elevator usually consists of malleable-iron buckets spaced at intervals and attached to the chain or belt by special attachments. The material is delivered into a boot from which it is scooped up by the buckets, elevated, and discharged by being thrown from the buckets by centrifugal force while passing over the head sprocket. Proper discharge action depends upon the diameter of head wheel, the speed and spacing of the buckets, and the location of the discharge chute. This type of elevator is satisfactory for the elevation of material containing no large lumps where nominal capacity is required. For fine, dry, or abrasive materials, a belt is usually used in place of chains. Where continuous service is required, it is better to use a slower speed elevator of the continuous-bucket type. Fine materials of light density should never be handled in a centrifugal elevator.

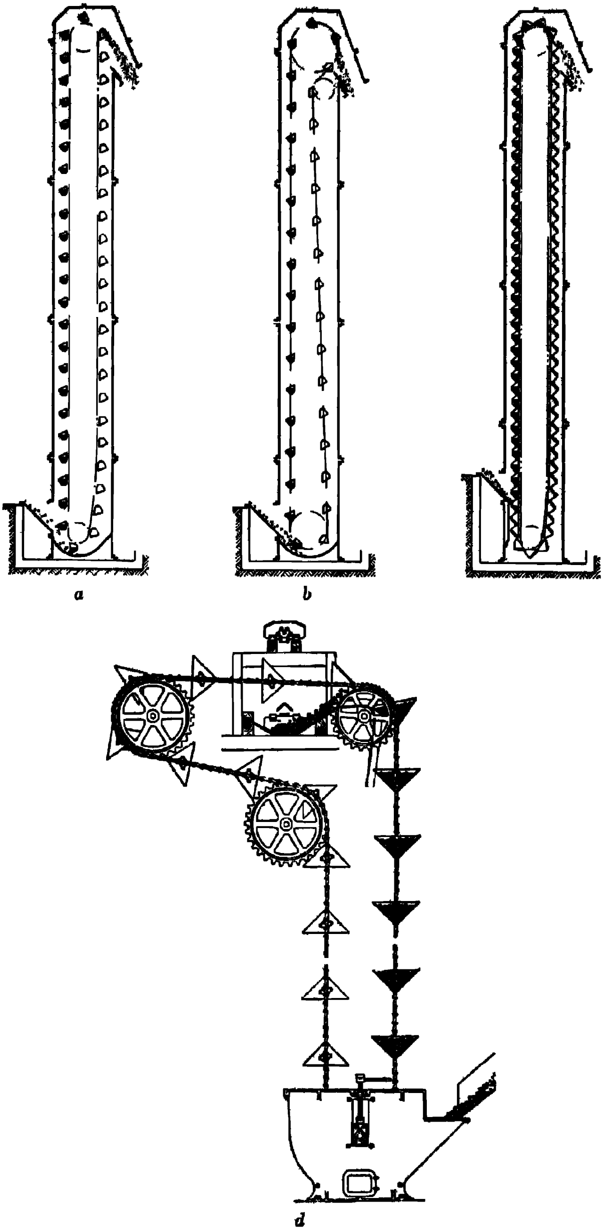

Fig. 20-5. Bucket-elevator types.

Perfect-discharge Type. The perfect-discharge bucket elevator (Fig. 20-5*b*) has buckets suspended at intervals between two strands of chain and operates at slower speeds than the centrifugal-discharge type. On the return side, just below the head wheels, are located a pair of idler sprockets to deflect the chains and completely invert the buckets. These idler sprockets may be omitted when the elevator is operated on an incline. Because of the slower speeds, fragile materials may be elevated without the breakage that would occur with the centrifugal-discharge type, and the operating parts wear longer.

Continuous Type. The continuous bucket elevator (Fig. 20-5*c*) consists of a continuous series of steel buckets on one or two strands of chain or a belt. The buckets are so shaped that the front of each will act as a deflector for the material being discharged from the succeeding bucket as it passes around the head wheel. Thus clean discharge is effected at the slow operating speeds (from 80 to 125 fpm). An inclination of the elevator will permit the discharge chute to be placed under the deflecting bucket, reducing spill.

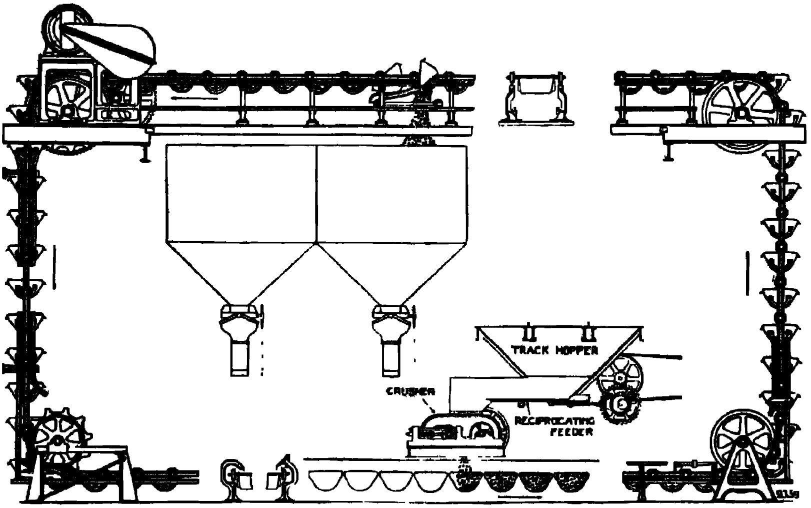

FIG. 20-6. Pivoted-bucket carrier.

A feeding leg is usually used, particularly with lumpy or abrasive material, in which the material is fed to the elevator two or three buckets above the foot wheel, eliminating the wear and strain of digging through an accumulation of material at the foot of the elevator boot. Elevators constructed in this manner are used extensively for the lifting of crushed stone, ore, coal, or other material of a bulky or gritty character and for certain light and fluffy materials.

The amount of material transported per hour by a continuous bucket elevator is relatively high, but the initial cost is higher than with the centrifugal- or perfect-discharge types, for more buckets are used, and since the loads are heavier, larger size machinery is required. However the lower maintenance of the continuous elevator will generally justify the additional cost.

Gravity-discharge Type. The gravity-discharge bucket elevator (Fig. 20-5*d*) was designed and is extensively used for elevating and conveying problems involving vertical and horizontal paths of operation or at inclinations up to 45 deg. The steel buckets, approximately V-shaped in cross section, are fastened between two strands of chain at right angles to the pitch of the chain. The material is scooped up from the boot as the buckets pass around the foot wheel and is elevated to the desired height where the buckets turn around the head wheel and trough-turn to a horizontal position of travel. Here the buckets push the material along a steel trough from which it may be discharged through gates or openings in the bottom of the trough.

By regulating the gates on the discharge run, the material may be delivered into any one of a number of bins. A number of bins may automatically be filled in series, for when the first bin is full, the material will obstruct the opening, and the following material will be carried on to the succeeding bin.

The slow speed (approximately 100 fpm) of the gravity-discharge type lessens degradation, for the pickup in the boot is slow, and the discharge may be down an inclined chute. This type is satisfactory for handling anthracite lump or run-of-the-mine coal, but ashes or gritty material will cause excessive wear to the horizontal troughs.

Pivoted-bucket Carrier. The pivoted-bucket carrier (Fig. 20-6) consists of a series of buckets pivotally suspended between two strands of roller chain and maintained in the carrying position by gravity. This permits a single carrier to transport vertically, horizontally, or on an inclined path. The buckets are usually constructed with a lip which overlaps the succeeding bucket while on the horizontal path and are fed while in this position. Discharge must be made on a horizontal run and is performed by a portable tripper overturning the bucket. This allows the discharge point to be varied along the length of the horizontal run. The buckets are either righted by gravity or by a separate device.

With this type of carrier, the power required is kept to a minimum as the friction losses are kept down by supporting of the bucket line on self-oiling rollers of large diameter. Elevating and conveying problems may be carried out through the use of one machine, and only one driving unit is required. Long life is attained through the slow operating speed (from 40 to 80 fpm) with smooth, quiet operation. Abrasive materials may be transported without undue wear. The system is economical to install and operate where the capacity and travel are not too great.

BULK CONVEYORS (See Table 20-2)

Flight Conveyors. The flight or pusher type of conveyor (Fig. 20-7) was developed as a means for distributing coal or other nonabrasive materials horizontally or at angles up to 45 deg. The material is received in a trough, pushed along by the flights or scrapers attached at intervals to a chain or chains, and discharged through gates in the bottom or at the end of the trough. Conveying is done on the bottom run.

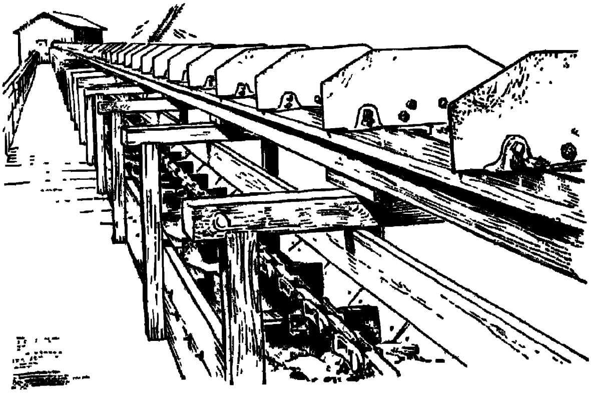

Fig. 20-7. Flight or pusher-type conveyor.

Flight conveyors are commonly used in boilerhouses and coal yards for the handling of coal which may be in the form of lumps or fines. The transporting of abrasive materials will shorten the life of the conveyor to a considerable extent. The maximum usable inclination is approximately 45 deg. With horizontal conveyors capacities may be up to 360 tons an hr of coal at a speed of 150 fpm.

Drag-chain Conveyors. Drag-chain conveyors are similar to flight conveyors in operation except that the flights are omitted, the conveyor consisting of nothing more than wide chain, of a suitable type, sliding in a trough and carrying the material with it. It operates at slow speeds (up to 20 fpm). A chain operating in a trough 20 in. wide and 8 in. deep, with a depth of material of 6 in., will carry 4.75 tons per hr of material weighing 50 lb per cu ft at a speed of 5 fpm. At other speeds and weights the capacities will be in direct proportion. Because of the slow speed, it is possible to handle abrasive materials with reasonable life if the chain and trough are constructed of hardened materials.

Conveying en Masse. The mechanism of the en masse conveyors (Fig. 20-8) appears much like a flight conveyor enclosed in a casing. It consists of a series of skeleton or solid flights (or a combination of the two) connected together with articulated joints to form a continuous chain. It operates over suitable pulleys, or pulley, and is enclosed within a dust-tight casing. A wide variety of operating paths varying from horizontal to vertical may be obtained. The feed may be at one or more points on either the upper or lower strands of a substantially horizontal run, while the discharge points may be on horizontal or at top of vertical runs.

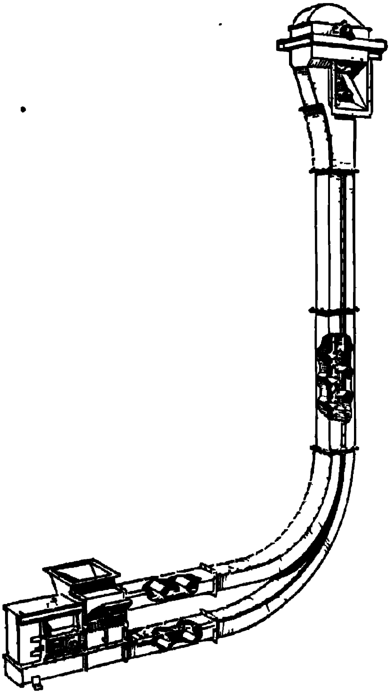

Fig. 20-8. En masse conveyor.

The space requirements for installation of the casing are small. The cross-sectional area required is less than one-fourth that of a flight conveyor, approximately one-fifth that of a bucket elevator, and one-third of a belt conveyor. Vertical casings are not self-supporting. While higher capacities are obtainable, it is recommended that, for requirements of over 100 tons per hr (50 lb per cu ft of material), another type of conveyor or elevator be used.

This conveyor is most suitable for handling pulverized or granular materials. Small lumps can be handled if they are not too large to enter or discharge. Corrosive, abrasive, or sticky materials should be avoided for the average installation.

Apron Conveyors. The apron conveyor is made up of overlapping steel pans which are carried between two strands of roller chain traveling on suitable tracks on both the top and bottom runs (see Fig. 20-9). Movable or stationary retaining sides may be used to permit a greater depth of material to be carried. Apron conveyors are used extensively for handling materials such as coal, ash, clinkers, sand, crushed stone, etc. A horizontal apron, 48 in. wide, with an average depth of 6 in. of coal and a speed of 50 fpm, will handle 100 to 110 tons per hr. Apron conveyors may be installed on inclines up to 25 deg.

Apron conveyors make excellent feeders from track hoppers. The feeder usually does not have sides on the pans but uses stationary skirt plates to retain the material on the conveyor. When used as feeders, they usually operate at a slower speed than when used as conveyors. A 36-in.-wide apron with 18-in.-high skirt plates will handle 45 tons per hr of coal traveling at 10 fpm.

The standard apron conveyor will withstand greater shock in the loading process than will other types of conveyors; however, in applications such as are encountered in the mining field, a more rugged conveyor is required. An apron conveyor of modified design will permit the carrying of lumps up to 6 ft in diameter and weighing a ton, and these lumps may be dropped onto the conveyor from a considerable height. The chains, rollers, sprockets, and overlapping pans are usually made of manganese steel. The chains are placed under the pans, away from the material, and the broad wearing surfaces of the chain links form substantial tracks for the closely spaced large-diameter rollers supporting the carrying run. On short feeders the return run is unsupported between the head and foot shafts. On medium- or long-center feeders, suitably spaced rollers carry the return run.

Reciprocating Plate Feeders. Reciprocating plate feeders are rather inexpensive units and are very satisfactory as a medium for feeding incline belt conveyors starting under track hoppers.

Screw Conveyors. The helical screw conveyor (Fig. 20-10) is particularly adaptable to the conveying of small-sized material such as grain, cement, cottonseed, pulverized coal, sand, etc. Where cleanliness or corrosion resistance is a factor, as in the food or chemical industries, the component parts may be made of special metals (brass, stainless steel, aluminum, etc.). In cases where abrasive materials are to be handled, hardened parts are used, and the screw may have a thickened wearing edge, replaceable if desired, or it can be stellited.

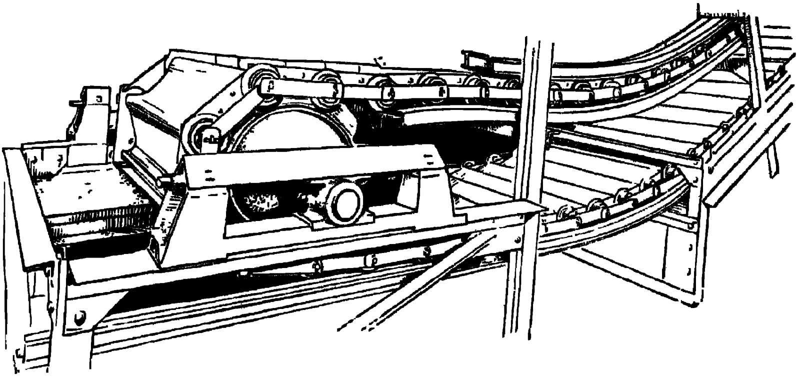

Fig. 20-9. Apron conveyor.

The diameter of the screw will vary from 3 to 24 in. and may be right hand, left hand, or a combination of the two (to move material either toward or away from the point of juncture). Where sticky materials are to be carried, a ribbon screw is used which has a clear space between the central shaft and the helix, eliminating the build-up of material along the shaft. If it is desired to have the conveyor act also as a mixer, separate paddles may be added to the screw shaft, or in the case of the ribbon conveyor, a second ribbon can be added inside the first but with opposing helix

Up to approximately 15 deg from the horizontal there is little decrease in the quantity of material conveyed, but above that point there is an appreciable decrease, the amount of which will depend upon the material, the air trapped in the material, and the pressure at the loading point. Installations up to the vertical are made with the pitch of the screw being reduced in such cases. Discharge may be over the end of the conveyor trough or through openings or gates in the bottom of the trough. The screw conveyor is especially applicable as a feeder. For free-flowing materials it will act as a shutoff when stopped. It can be installed within relatively small space limitations.

Vibrating Conveyors. Vibrating conveyors consist of a single-piece steel (or other material) deck to serve as the carrier with the vibratory motion imparted by a mechanical, electric, or hydraulic drive. On one device of the mechanical type, the deck is supported on pairs of legs hinged at each end. The lower ends of the legs are ahead (considering the direction of travel of the material) of the upper ends (Fig. 20-11).

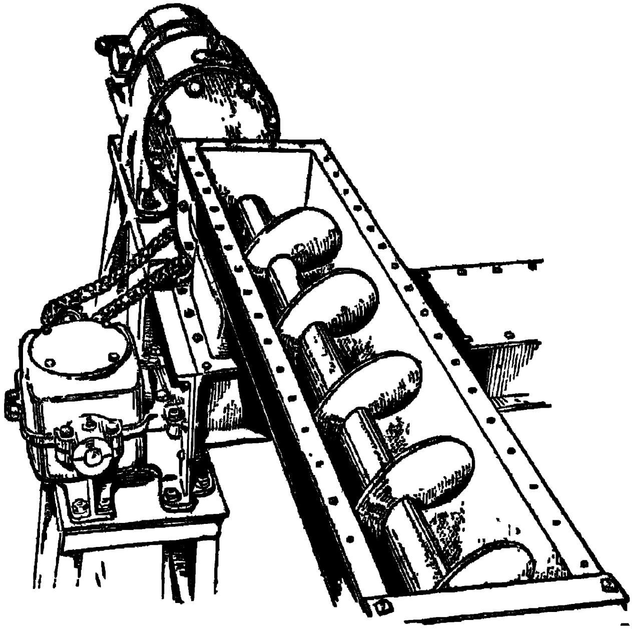

FIG. 20-10. Helical screw conveyor.

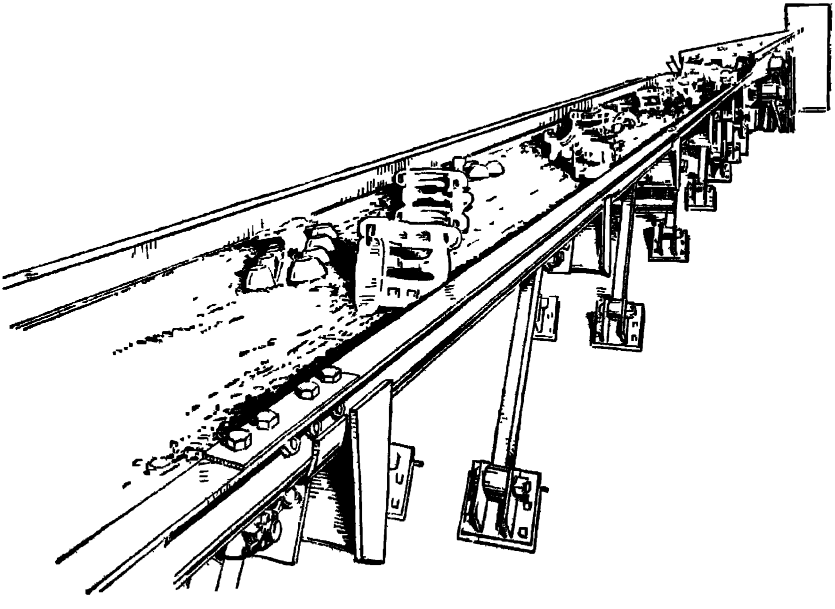

FIG. 20-11. Vibrating conveyor

Thus, as oscillatory motion is imparted to the deck by a short throw crank, an upward and forward thrust is obtained, and the material will "float" along, being held in suspension most of the time by the motion of the trough. The rate of movement will be from 20 to 50 fpm.

Another type of vibrating conveyor has the deck suspended or supported on coil springs or cushions. An electric driver or drivers, of the magnet or solenoid type, is attached to the underside of the deck at an angle of about 20 deg from the horizontal. As a series of a-c or interrupted d-c pulses is applied to this "motor," a vibration of the deck is obtained both vertically and horizontally, causing the material to "flow" along the deck. These conveyors are manufactured in various sizes handling up to 200 tons per hr, level operation. The speed of material movement may be varied by changing the amplitude of the vibrations through control of the amount of electric current supplied.

A vibrating conveyor is ideally suited for the handling of materials that would produce unsatisfactory results with most other types of conveyors, such as metal turnings, borings and chips, steel scrap, castings, shakeout sand, and material that is abrasive, wet, oily, hot, and jagged or irregular in shape. For dust control, the conveying decks may be enclosed pans, rectangular or circular. Flake material may be handled up a slight incline. The conveyor may be combined with screens or grizzlies for selective separation of the material.

Belt Conveyors. The principal elements of belt conveyors are a belt, usually rubber covered (see Power Belting, Fasteners, Pulleys, and Shafting in Sec. 14), two end pulleys, the driving machinery, and usually a series of intermediate supporting pulleys. The intermediate pulleys, or idlers, may consist of one, three, or five separate rollers. In the case of multiple rollers, the outer ones are inclined to trough the belt, increasing its carrying capacity without spill. Roller or ball bearings on the idlers are used to decrease the friction losses and to lessen the maintenance required. The carrying idlers should be from 3 to 5 ft apart, depending upon the capacity required, the size of lumps, and the weight of material per cubic foot. The spacing of the return idlers may be 9 to 10 ft apart. Pneumatic idlers are used to lessen the effects of shock at loading points where it cannot be avoided.

To reduce the wear on the belts, the loading should be in such a manner that the material striking the belt will have an initial velocity approximately equal to that of the belt and in the same direction. Where a mixture of lumps and fines is handled, it is best to have the fines loaded on the belt first to provide a cushion for the loading of the lumps. Stationary skirtboards, a slight distance above the belts, are often used at the loading point to eliminate spill.

Discharge may take place over the head pulley, or stationary trippers may be installed at predetermined points along the path of travel. Where it is desired to unload at a number of points, a movable tripper may be installed which will allow discharge at any point along the travel of the belt but not closer than approximately 20 ft from the loading end. Headroom may be a factor with tripper installations since they require from 4 to 7 ft above the conveying belt. For slow-speed belts, installed flat, a strike-off board may be used to act as a plow in removing the material from the belt.

Belts operate at speeds from 300 to 600 fpm (higher when carrying grain) and may be from 12 to 60 in. wide. Because of their high speed and continuous delivery of material, the quantity carried per hour will be relatively high. A 60-in. belt carrying coal (50 lb per cu ft) at 600 fpm will carry 2,160 tons per hr. They can be operated at inclines up to approximately 18 deg, depending upon the physical characteristics of the material.

Owing to the large continuous capacity, with low power consumption, the cost per ton for belt conveying is relatively low. Belt conveyors are simple in construction and relatively noiseless in operation. A number of interesting bulk-material handling problems have been solved through the use of belts, such as the Shasta Dam construction on the Sacramento River, California. Concrete aggregates were carried 9.6 miles on twenty-six 36-in.-wide belt conveyors, operating at 550 fpm with a capacity of 1,100 tons an hr.

Portable Loaders and Unloaders. A number of portable loaders and unloaders are made, using belts, and are particularly adaptable for intermittent operation where the total volume per day is small. A boxcar loader is produced which is wheeled to the car door where it can be supplied by another conveyor or from a chute. The belt is run at high speed which serves to throw the material as far as either end of the car, distributing it for proper loading.

A larger unit, mounted on a permanent base, beside or between loading tracks, has hinged and pivoted arms supporting the belt mechanism to allow the loader to be swung into the car. A slow-speed belt is used, the arms having sufficient movement to reach either end of the car and deposit the material without throwing. Degradation is kept at a minimum by the gentle deposit of the load.

A belt made of a band of 0.65-carbon cold-rolled steel, 0.03 or 0.04 in. thick, is available in widths up to 32 in. These belts operate flat, usually handling materials that are injurious to rubber and fabric belts. Woven-wire belts are used on conveyors that wash, dry, heat, or cool material. Their open structure permits liquid to drain from the material and permits air to circulate freely. This wire can be of a metal that will resist corrosion or great heat.

Bulldozers, Carryalls, and Drag-line Scraper Buckets. Bulldozers, carryalls, and drag-line scraper buckets are generally considered for building up outdoor stock piles and for reclaiming same.

PACKAGE HANDLING

In package handling the material is in unit form: cartons, boxes, barrels, sacks, or pieces in their semifinished or finished state. The characteristics of the units and the purpose of moving them determine the device to be used for any particular problem (see Figs. 20-12 and 20-13).

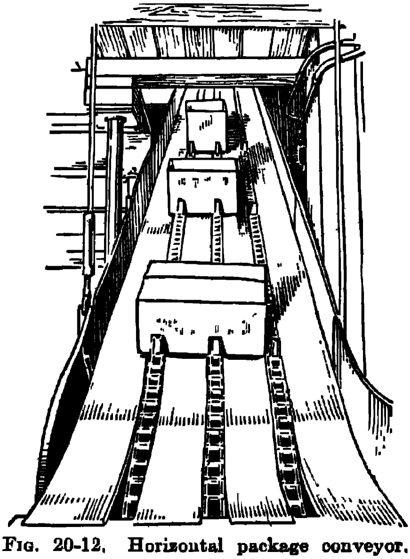

FIG. 20-12. Horizontal package conveyor.

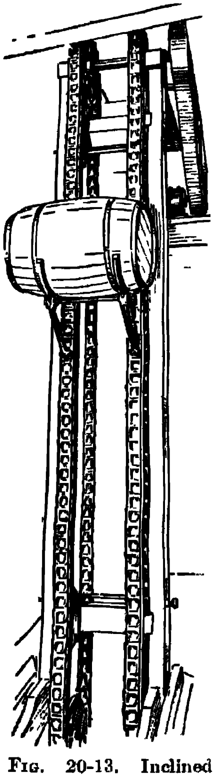

FIG. 20-13. Inclined package conveyor.

Elevators. A belt or a pair of chains, operating vertically or on an incline, may have rigidly attached protruding arms suitable for the package. In loading for upward travel, the package is placed on a finger skid. The ascending arm passes through the skid and picks up the package. The discharge is usually over the head wheel where a fingered chute will catch the package while permitting the arm to pass through. If it is desired to discharge on the ascending run, the arms can be arranged to discharge on contact with suitable mechanism at the desired unloading level.

An elevator may have carrying trays pivotally suspended between two strands of chain, with the center of gravity of the trays and load low enough to maintain them in an upright position. The carrying trays consist of transverse fingers which mesh with similar fingers in the loading and discharge skids. The load is placed on the skid from which it is picked up by the ascending tray, carried over the head wheel, and discharged on the descending side at the first point a skid is encountered.

A reciprocating lift can be used for elevating drums on end, cartons, tote pans, etc. This device can be made to function on a semi- or fully automatic basis. It also can be arranged to lower packages by merely providing the necessary electric controls.

Portable Elevators. A number of different types of portable elevators, stackers, or tiering machines are made with the lifting mechanism either motor or hand operated. Various methods of guiding the vertical path of the lifting tray are used. One type has a turntable base to allow use in restricted quarters, such as narrow aisles. The maximum size of a standard unit is approximately 2½ tons with an 18-ft lift.

Portable stackers are made for the handling of smaller units. Some of these inclined stackers use a belt with or without transverse cleats. Others have chains with flights to push the loads up an inclined chute.

Gravity Roller Conveyors. Gravity roller conveyors, consisting of ball-bearing mounted tubes or pipes, are generally used to convey packages short distances and around curves. The permissible distance is determined by practical loading height and by the normal pitch required of approximately ½ in. per lin ft. Horizontal runs of gravity can be used to move heavy masses by hand as the rolling resistance will be from 1 to 3 per cent. Roller curves also are combined to form a lowering spiral which serves as satisfactory supply to filling machines or to a loading dock. For long horizontal distance, where a supply of containers is to be stocked for ready use, the roller conveyor can be made "live" by an actuating drive belt placed under the carrying roller (known in the industry as "live roller conveyor").

Spiral Chutes. Spiral chutes, made in the form of a vertical helix with a guardrail, are universally used as a cheap and practical means for lowering most types of packages except steel drums.

Conveyors. Belt conveyors, operating horizontally or inclined, may be used for the handling of large or small packages. For small, light packages, the carrying run of the belt may be slid along a flat surface to provide the necessary support. For heavier loads, rollers are used to carry the load. The rollers will usually be smaller and closer together than those used with bulk-material conveyors. To eliminate bumping, the package on the belt should be supported by no less than two rollers at any time. Packages may be handled on inclines up to approximately 25 deg through the use of crepe-top belts. The belt speeds are generally less than when handling bulk material.

Slat conveyors have transverse wooden or metal slats connected to and moved by one or two endless chains. The weight may be carried by the slats sliding on a pair of tracks, but the better practice is to have the slats fastened to roller chains; the weight is rolled, and friction is less.

A push-bar conveyor uses a continuously moving chain to which are attached flights or pushers to provide the impetus for the movement of packages. The amount of inclination that can be attained with this type is limited only by the overturning of the packages.

A number of wheeled carts can be attached to an endless chain. This system is commonly used in foundries. The flasks are loaded on the carts at the molding machine, poured, and transported to the shakeout in a continuous movement. From the shakeout the empty flasks may be returned to the molder on the same cart.

Chain conveyors are used with the article carried directly on single or multiple runs of chain sliding in guide troughs. Stationary skirtboards may be employed to prevent side movement of the article on the chain. Where inclines or declines are required, raised lugs on the chain prevent slipping of the article. Normal chain speeds will be approximately 30 fpm.

Overhead conveyors consist of small wheels operating on one or two rails with suitable carriers suspended therefrom. The wheels are connected by an endless conveyor chain driven by a sprocket or a second short drive chain with protruding dogs (known as a "caterpillar drive") to engage and transmit motion to the conveyor chain. Overhead conveyors may follow a wide variety of paths: up or down steep inclines, around short-radius horizontal curves. The conveyor is usually suspended from above and does not require floor space.

Overhead supported telphers or tramrails are also used. By the use of a number of tracks and switches these machines are not limited to one fixed pattern of operation but have some flexibility in moving material from one department to another.

Hoists and Grabs. Hoists and grabs are generally used in conjunction with jibs, monorails, or cranes to raise and transport carrier racks, charging hoppers, and miscellaneous objects. The hoists can be chain actuated for light loads or can be powered by air, hydraulic, or electric means for handling heavier or more frequent loadings. Many forms of standard and special grabs have been developed for engaging most of the objects or shapes encountered in industry.

SKID AND PALLET HANDLING

A pallet is nothing more than a portable platform on which objects are placed to facilitate their handling. The universal use of pallets was given impetus by Army and Navy shipping requirements during the Second World War.

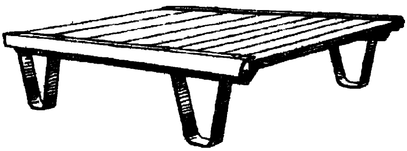

Fig. 20-14a. Skid.

The pallets used today by industry for the easy handling of one or multifold units in a single load are constructed with a base raised a short distance from the floor to allow the tines of a fork truck to be inserted underneath to raise the load. Similar to the industrial-type trailers are the "live" skids which are mounted on wheels, usually of the rigid-caster type. This allows short movements to be made without engaging the tine of a fork truck, but they are carried or pulled by a fork truck during long movements

More common are the skid (Fig. 20-14a) which is supported on legs and the pallet (Fig. 20-14b) which rests on a flat base. In addition to being less expensive, pallets have the advantage that they, with loads, can be stacked in tiers to accomplish space saving in storing or warehousing operations. The standard size of a pallet is 4 by 4 ft. They may be manufactured of wood, metal, or a combination of the two.

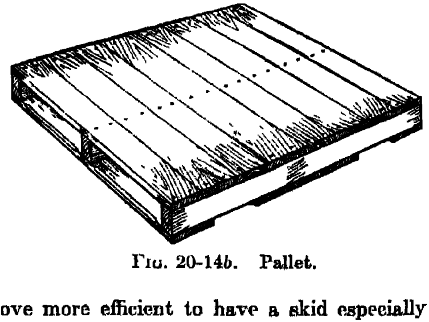

Fig. 20-14b. Pallet.

In the handling of large individual units or where plant requirements are such that special "skid boxes" are impractical, the flat skid may be the most suitable. Figure 20-15 illustrates such a metal skid being handled with a fork truck. For other applications it may be more suitable to have a container box, racks, or multiple trays mounted on the skid. In many cases it will prove more efficient to have a skid especially designed for the conveying problems encountered in the particular plant (Fig. 20-16)

The use of pallets not only affords the advantage of ease and flexibility of handling materials throughout the plant but allows rapid loading and unloading of trucks and boxcars. For plants having only intermittent loading and unloading problems, a fork truck need be freed from its other duties for only a short interval to complete the job so that plant investment is not tied up in a mechanical device that is idle a considerable portion of the time.

Pallets or skids used for shipping may be any of the general type. With the flat-skid type it may be advisable in many cases to secure the load to the skid with metal straps, while the use of adhesives between the individual packages on the load may reduce the number of straps required. If container-type pallets used for shipping are to be returned for reuse, they should be constructed so they can be "knocked down" to effect a space saving that will allow a large number to be returned in one load.

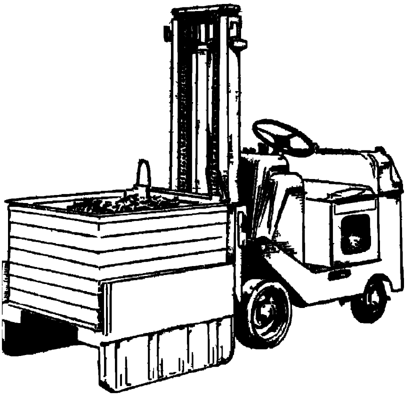

Fig. 20-15 Metal skid being handled by fork truck

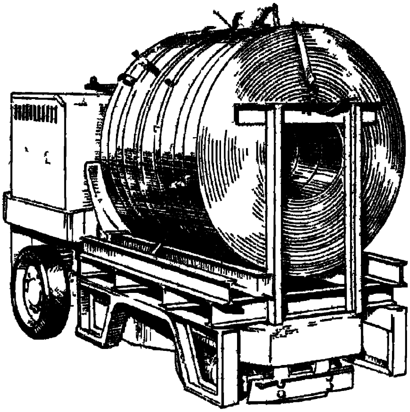

Fig. 20-16 Skid of special design to suit the object to be handled

The prevailing method of pallet or skid handling is by the use of fork trucks. These are produced for hand operation, or they may be driven by gasoline engine or electric motor, battery supplied. Powered models are available up to capacities of 9 tons and lifts up to approximately 25 ft. In many cases it will be economical to use one or more of the package conveyors, previously discussed, alone or in conjunction with fork trucks, for specific handling operations. Loads consisting of quantities of long items (pipe, lumber, steel, etc.) may be handled on larger bolsters through the use of straddle trucks, as shown in Fig. 20-17.

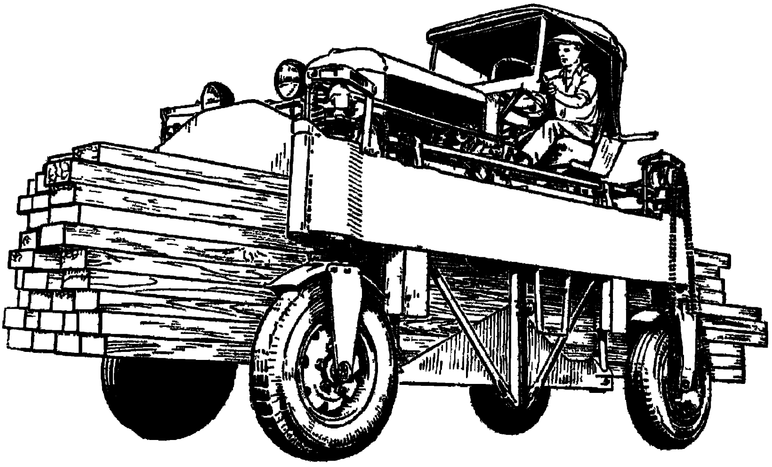

Fig. 20-17 Straddle truck for the handling of pipe, lumber, steel, etc.

CONVEYOR AND CONVEYOR-BELT ENGINEERING

BY CHARLES W. STAACKE

Special Assistant to President, Hewitt-Robins, Inc., Formerly Belting Engineer, B. F. Goodrich Company

INTRODUCTION

Before starting the design of a belt conveyor, the following information must be available:

1. Kind of material to be handled and its weight per cubic foot, maximum size, condition of the material, such as wet, dry, hot, oily, acid, etc.
2. Quantity to be handled in terms of maximum short tons per hour
3. Distance to be conveyed and the height to elevate or lower

With this information, the necessary belt width required for these conditions can then be determined. The width is considered in conjunction with belt speed in feet per minute (Table 20-10), the maximum material size (Table 20-14), and the angle of incline (Table 20-16). Also see Tables 20-12 and 20-15.

Other factors such as type of feed, balancing conveyor drives for uniformity of motors, speed reducers, standardization of belt widths and plies, breakage of material, and spillage must also be considered.

The next step is to decide on the type and location of the belt-driving mechanism and the take-up.

The foregoing information is necessary to calculate

1. Total power the belting must transmit. See Solving for the Total Horsepower the Belting Must Transmit, page 1420, which gives the necessary steps to follow.
2 Convert this total power, horsepower, into terms of maximum belting working stress in pounds. This starts with Converting Total Horsepower Belting Must Transmit into Maximum Belt Stress in Pounds (T_M). Nine different conveyor examples, Figures 20-18 to 20-26, inclusive, follow this heading.
3. Decide on the correct belt-carcass construction (see page 1426).
4. Determine cover thicknesses to be used (see pages 1428 and 1429).
5. Equipment over which the belting must operate and suggestions for same (see pages 1429 and 1430).

SOLVING FOR THE TOTAL HORSEPOWER THE BELTING MUST TRANSMIT

Solving for the total horsepower the belting must transmit is divided into three main factors.

1. Horsepower to overcome friction in all the moving parts that are belt driven. This is factor X.

$$X = (G \times F_x \times S \times L_c)/33{,}000$$

2. Horsepower required to move the load horizontally (without lift or drop). This is factor Y.

$$Y = (L_c \times F_y \times C)/990$$

3. Horsepower required to elevate the load or the power generated by the load moving downhill. This is factor Z.

$$Z = (C \times H)/990$$

(This power is plus for upgrade and minus for down.)

NOTE: If there are belt-driven conveyor accessories such as trippers, feeders, cleaners, etc., more power will have to be added for them (see page 1436 for extra power to add for trippers).

The total power transmitted by the belt then equals horsepower and is the algebraic sum of the above three factors.

$$\text{Hp} = X + Y + Z \qquad \text{or} \qquad \text{Hp} = X + Y - Z$$

as the case may be.

In the above three formulas

G = weight, lb per ft, of center distance over the belting of all moving parts that are belt driven, plus the weight of 2 ft of belting (see Tables 20-17, 20-18, 20-19, and 20-20)

F_x, F_y = friction factors (see Table 20-21)

C = *maximum* rate of feed to the belting, short tons (2,000 lb) per hr (see Table 20-12)

S = belt speed, fpm

L = center-to-center distance measured over the belting between the head and tail pulleys

L_c = corrected center distance ($L_c = 0.55L + 115$)

H = total vertical lift or drop (including tripper height) measured from point of loading onto the belt to the point of discharge from the belt, ft

NOTE: The total horsepower the belting must transmit does not include the power losses in the driving motor or motors or in the reducing unit (see page 1436 for instructions in determining the correct motor size needed to compensate for these losses).

CONVERTING TOTAL HORSEPOWER BELTING MUST TRANSMIT INTO MAXIMUM BELT STRESS IN POUNDS (T_M)

Converting total horsepower belting must transmit into maximum belt stress in pounds (T_M) is done by using two fundamental formulas for power transmission by belting:

$$\text{Hp} = [(T_1 - T_2)S]/33{,}000 \qquad \text{or} \qquad T_1 - T_2 = (\text{hp} \times 33{,}000)/S = T_E \qquad (1)$$

$$(T_1 - T_c)/(T_2 - T_c) = 10^{0.00758fa} \qquad \text{or for conveyors} \qquad T_1/T_2 = 10^{0.00758fa} \qquad (2)$$

where $T_1 - T_2 = T_E$ = the effective tension, or the difference between the theoretical tight-side tension T_1 and the theoretical slack-side tension T_2 at the conveyor drive. In the case of tandem- or dual-motor drives, an intermediate belt tension T_3 exists between the two driving pulleys

S = belt speed, fpm

Hp = total power the belting must transmit

$T_c = Wv^2/g$ = belt tension due to centrifugal force which for conveyor speeds is so small that it can be neglected (W = belt weight per lineal foot, lb; v = belt velocity, fps; and $g = 32.2$)

f = coefficient of friction between belting and the drive pulley or pulleys. 0.25 is used between rubber-belting covers and bare-steel or cast-iron pulleys and 0.35 between rubber-belting covers and rubber lagging. These figures are used for either wet or dry conditions. If rubber lagging is frequently wet, a grooved-design lagging should be used to prevent excess slippage between the belting and the lagging

a = total arc of contact between the belt and the driving pulley or pulleys, deg

For any given set of driving conditions, by solving simultaneously Eqs. (1) and (2) above, both T_1 and T_2 can be determined. That is assuming that horsepower, speed, and the other factors are known or assumed except T_1 and T_2.

Instead of doing this, it is much simpler to use Table 20-22. This table gives values to a drive factor K for any set of driving–take-up combinations, with bare or lagged pulleys.

Multiplying the effective tension T_E by this factor will give the theoretical slack-side tension T_2 needed in the belting at the drive to enable the belting to transmit the required horsepower without slippage occurring. Thus

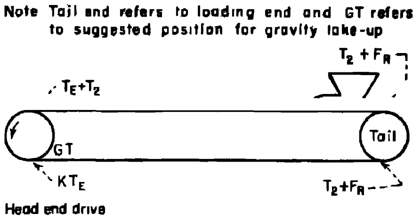
$$T_1 - T_2 = T_E = (\text{hp} \times 33{,}000)/S \qquad T_2 = KT_E,$$

and substituting this value of T_2 in Eq. (1),

$$T_1 = T_E + T_2 \qquad \text{or} \qquad T_1 = (K + 1)T_E$$

For many drives T_1 equals the maximum belt tension T_M. However, there are cases where T_1 is not the maximum tension and where T_2 is considerably more than the theoretical value needed to prevent slipping between the belting and the drive pulley or pulleys. These variations are due to drive location and depend upon whether the belt conveyor is an elevating or a lowering one. The effect of belt weight on a slope becomes a very important factor particularly on long-center, high-lift, or decline conveyors.

This belt-slope weight equals HW, where H is total lift or drop in feet, and W is belt weight per lineal foot. But the return idlers have a retarding action which tends to lessen this weight or pull. The idler retarding force equals $0.4(G \times F_x \times L_c)$ (see Table 20-18 for figuring belt weights).



Note Tail end refers to loading end and GT refers to suggested position for gravity take-up
$T_2 + F_R$
$T_E + T_2$
GT
Tail
KT_E
$T_2 + F_R$
Head end drive

FIG. 20-18. Approximately horizontal conveyor with drive at or near head end.

$T_E = (\text{hp} \times 33{,}000)/S$
$T_2 = KT_E$ = theoretical slack-side tension
$T_1 = T_E + T_2$ or $(K + 1)T_E$
$T_M = T_1$

To simplify the calculations for various types of conveyors, typical examples are given by Figs. 20-18 to 20-26, inclusive. These show drive and take-up location and the steps necessary to arrive at the maximum belt working stress T_M.

NOTE: This notation applies to Figs. 20-18 to 20-26, inclusive. Since it is usually necessary to increase the take-up weight over the theoretical amount, it is suggested that 2 per cent of the T_1 value be added to the theoretical maximum tension T_M to estimate the maximum operating tension.

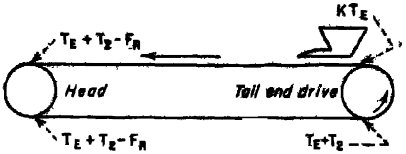


Fig. 20-19. Approximately horizontal conveyor with drive at or near tail.

T_E = (hp × 33,000)/S

$T_2 = KT_E$ = theoretical slack-side tension

$T_1 = T_E + T_2$ or $(K + 1)T_E$

$T_M = T_1$

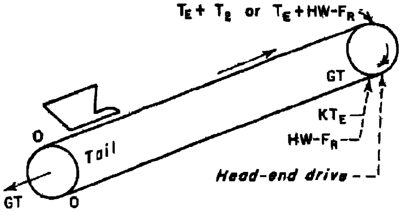

Fig. 20-20. Elevating conveyor with drive at or near head end.

T_E = (hp × 33,000)/S

$T_2 = KT_E$ = theoretical slack-side tension

$T_1 = T_E + T_2$ or $(K + 1)T_E$

The effect of return-side belt tension = $HW - F_R$. If T_2 is greater than $HW - F_R$,

$$T_M = T_1 = T_E + T_2$$

If T_2 is less than $HW - F_R$,

$$T_M = T_E + HW - F_R \quad \text{or} \quad T_1 - T_2 + HW - F_R$$

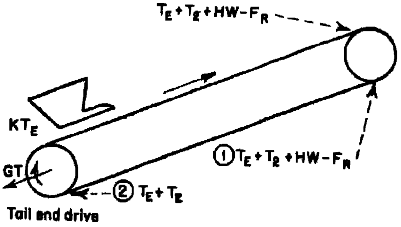

Fig. 20-21. Elevating conveyor with drive at or near tail end.

T_E = (hp × 33,000)/S

$T_2 = KT_E$ = theoretical slack-side tension

$T_1 = T_E + T_2$ or $(K + 1)T_E$

The effect of return-side belt slope tension = $HW - F_R$. If HW is greater than F_R, then maximum tension is at ①, and

$$T_M = T_E + T_2 + HW - F_R \quad \text{or} \quad T_1 + HW - F_R$$

If HW is less than F_R, then maximum tension is at ②, and

$$T_M = T_1 = T_E + T_2$$

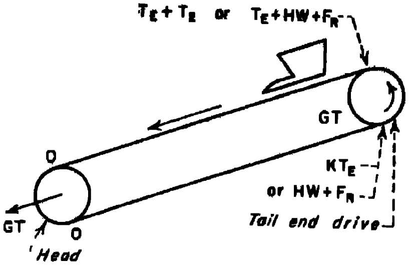

FIG. 20-22. Lowering conveyor with tail-end drive (holdback).

Suppose that in the horsepower calculation for a lowering conveyor, $X + Y - Z$ came out to be a negative number, which meant that Z was greater than $X + Y$. The fully loaded belt would tend to run down the slope, and holdback force is necessary at the drive.

$$T_E = (\text{hp} \times 33{,}000)/S$$
$$T_2 = KT_E = \text{theoretical slack-side tension}$$
$$T_1 = T_E + T_2 \qquad \text{or} \qquad (K + 1)T_E$$

The effect of return-side belt tension $= HW + F_R$. If T_2 is greater than $HW + F_R$,

$$T_M = T_1 = T_E + T_2$$

If T_2 is less than $HW + F_R$,

$$T_M = T_E + HW + F_R \qquad \text{or} \qquad T_1 - T_2 + HW + F_R$$

Caution: In most lowering conveyors, the T_E and T_2 tensions required for the empty conveyor are greater than for the loaded. Therefore the T_K used for the maximum-tension calculation should be the T_E calculated on basis of the horsepower X or the horsepower $X + Y - Z$, whichever is the larger.

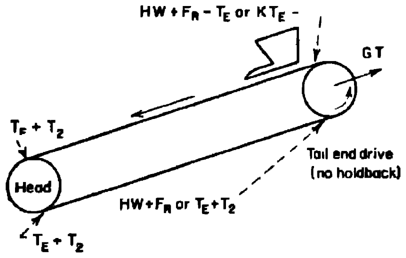

FIG. 20-23. Lowering conveyor with tail-end drive (no holdback).

Suppose that in the horsepower calculation for a lowering conveyor, $X + Y - Z$ came out to be a positive value, which meant that $X + Y$ was greater than Z. The loaded belt will then not tend to run down the slope but will always require some power, and no holdback will be necessary.

$$T_E = (\text{hp} \times 33{,}000)/S$$
$$T_2 = KT_E = \text{theoretical slack-side tension}$$
$$T_1 = T_E + T_2 \qquad \text{or} \qquad (K + 1)T_E$$

The effect of return-side belt slope tension $= HW + F_R$. If T_2 is greater than $HW + F_R - T_E$,

$$T_M = T_E + T_2 \qquad \text{or} \qquad T_1$$

If T_2 is less than $HW + F_R - T_E$,

$$T_M = T_E + HW + F_R - T_F = HW + F_R$$

Caution: In most lowering conveyors, the T_F and T_2 tensions required for the empty conveyor are greater than for the loaded. Therefore the T_E used for the maximum tension calculation should be the T_E calculated on the basis of the horsepower X or the horsepower $X + Y - Z$, whichever is the larger.

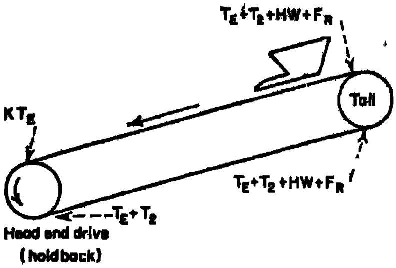

FIG. 20-24. Lowering conveyor with head-end drive (holdback).

Suppose that in the horsepower calculation for a lowering conveyor, $X + Y - Z$ came out to be a negative value, which meant that Z was greater than $X + Y$. The fully loaded belt would tend to run down the slope, and holdback is necessary at the drive.

$$T_E = (\text{hp} \times 33{,}000)/S$$
$$T_2 = KT_E = \text{theoretical slack-side tension}$$
$$T_1 = T_E + T_2 \quad \text{or} \quad (K + 1)T_E$$

The effect of return-side belt slope tension $= HW + F_R$.

$$T_M = T_E + T_2 + HW + F_R \quad \text{or} \quad T_1 + HW + F_R$$

Caution: In most lowering conveyors, the T_E and T_2 tensions required for the empty conveyor are greater than for the loaded. Therefore the T_E used for the maximum tension calculation should be the T_E calculated on the basis of the horsepower X or the horsepower $X + Y - Z$, whichever is the larger.

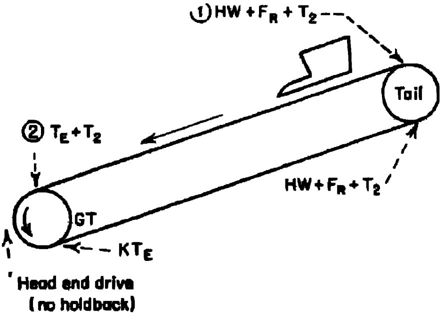

FIG. 20-25. Lowering conveyor with head-end drive (no holdback).

Suppose that in the horsepower calculation for a lowering conveyor, $X + Y - Z$ came out to be a positive value, which meant that $X + Y$ was greater than Z. The loaded belt will not tend to run down the slope but will always require some power, and no holdback will be necessary.

$$T_E = (\text{hp} \times 33{,}000)/S$$
$$T_2 = KT_E = \text{theoretical slack-side tension.}$$
$$T_1 = T_E + T_2 \quad \text{or} \quad (K + 1)T_E$$

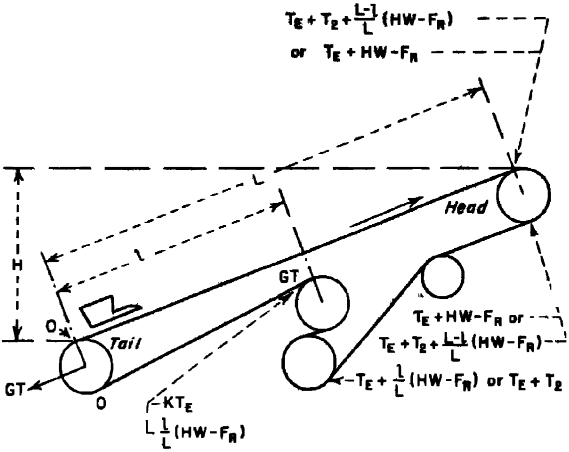
The effect of return-side belt-slope tension $= HW + F_R$. If $HW + F_R$ is less than T_E,

$$T_M = T_1 = T_E + T_2 \text{ and is at ②}$$

If $HW + F_R$ is greater than T_E,

$$T_M = HW + F_R + T_2 \text{ and is at ①}$$

Caution: In most lowering conveyors, the T_E and T_2 tensions required for the empty conveyor are greater than for the loaded. Therefore the T_E used for the maximum tension calculation should be the T_E calculated on the basis of the horsepower X or horsepower $X + Y - Z$, whichever is the larger.



$T_E + T_2 + \frac{L-l}{L}(HW - F_R)$
or $T_E + HW - F_R$

$\frac{l}{L}(HW - F_R)$
$T_E + HW - F_R$ or
$T_E + T_2 + \frac{L-l}{L}(HW - F_R)$
$T_E + \frac{l}{L}(HW - F_R)$ or $T_E + T_2$

FIG. 20-26. Elevating conveyor with tandem or dual motor drive located part way down the slope on the return side.

$$T_E = (\text{hp} \times 33{,}000)/S$$
$$T_2 = KT_E = \text{theoretical slack-side tension}$$
$$T_1 = T_E + T_2 \quad \text{or} \quad (K + 1)T_E$$

The effect of return-side belt-slope tension $= (l/L)(HW - F_R)$. If T_2 is greater than $(l/L)(HW - F_R)$,

$$T_M = T_E + T_2 + (L - l)/L(HW - F_R)$$

If T_2 is less than $(l/L)(HW - F_R)$,

$$T_M = T_E + HW - F_R$$

DETERMINING TYPE AND NUMBER OF PLIES NECESSARY

The type and number of plies necessary must be

1. Sufficient to withstand the maximum belt operating tension T_M
2. Sufficient for the proper support of the load between idlers
3. Of sufficient body to withstand the impact at the loading point
4. To a minimum number for the belt width being considered so that there will be proper troughability when belt is empty or lightly loaded

The permissible working stresses for the various conveyor-belting fabrics and constructions, as given in Table 20-4, are based on actual strengths of the material used and the application of a suitable factor of safety. This factor of safety takes into consideration the higher stress in the belting when it is being started from rest either loaded or empty.

Determining Number of Plies Necessary for Maximum Tension

For fabric or cord belts through the No. 100 construction,

$$\text{Number of plies} = \frac{T_M}{\text{belt width (in.)} \times \text{permissible stress (lb/in./ply)}}$$

For steel-cord belts,

$$\text{Construction} = T_M/\text{belt width (in.)}$$

With the steel-cord constructions, the belting will have sufficient body to support the load and resist impact, and in addition these belts will trough satisfactorily in 24-in. or wider widths. In the case of the fabric and other belt constructions, it is necessary to consider the maximum and the minimum number of plies that can be used for any given belt width (see Table 20-23).

To get the best service from any conveyer belt and to take advantage of the strength that is built into it, it is desirable to make the belting endless by means of vulcanized splices rather than with metal fasteners. Table 20-4 gives separate columns of figures for metal or vulcanized splicing. In the case of the cord belt constructions, to take full advantage of the qualities built into the belting, it is preferable to use vulcanized splices. However, by proper balancing of base plies of fabric and the cord plies, it is possible to use the cord belting with metal fasteners. Note, however, if metal lacings are employed, the No. 50 type should be used, not types No. 70 or No. 100. See Table 20-5 on balancing No. 50 cord construction for vulcanized and metal splicing.

Table 20-4. Permissible Working Stresses

Belt duck weight, oz	Permissible stress, lb per in. per ply	
	Vulcanized splices	Metal fasteners
28	31	26
32	36	30
36	41	35
42	50	40
No 50 cord	50	40*
No 70 cord	70	40*
No. 100 cord	100	40*

* Refer to Table 20-5

Steel cord	*Permissible stress, lb per in of belt width*
No. 1000	1 000
No. 1500	1,500
No. 2000	2,000
No 2500	2,500
No. 3000	3,000

Note: It is suggested that, before using the No. 70, No. 100, or any of the steel-cord constructions, complete operating details be referred to the belting manufacturer and to the equipment manufacturer The initial cost of the investment in these latter constructions warrants the best in equipment design and operating maintenance, and such installations should not be considered as just ordinary conveyor installations.

Belt Flexibility

1. Sometimes a few heavy plies are better than a larger number of lighter plies.
2. Cord carcass is superior because of greater cushion and greater strength with no loss of troughability.
3. Twenty-eight-ounce fabric is indicated only for the lightest service.
4. High working stress, heavy load, large lumps, heavy impact indicate need for 42-oz fabric or cord construction.

Standardization

Wherever possible in a plant using a number of conveyors, it is desirable to standardize on one construction for each of the belt widths used. This will simplify the problem of keeping spare belting on hand. It is necessary in doing this that the belt decided upon be properly designed for the hardest service.

Table 20-5. Cord Conveyor-belt Ply Combinations

Total plies	Cord construction No. 50 with vulcanized splices		Cord construction No 50 when necessary to use metal fasteners	
	Fabric plies	Cord plies	Fabric plies	Cord plies
4	2	2	2	2
5	2	3	2	3
6	2	4	3	3
7	2	5	3	4
8	2	6	4	4
9	2	7	4	5
10	2	8	5	5

Note: With vulcanized splices, the permissible working stress in the above combinations is 50 lb and with metal splices, 40 lb.

DETERMINE COVER THICKNESSES

Before the Second World War the various rubber companies were making four qualities of belt-cover stocks. During the war these were reduced to two, and since that time they have standardized on three grades. (This is exclusive of special constructions for oil, heat, or other special services.)

Table 20-6 gives brand comparisons for the three standard constructions furnished by all of the major rubber companies.

In deciding on the cover thickness to be used consideration should be given the following:

1. Quality of rubber to be used
2. Thickness to be used
3. Type of breaker to be used if one is needed

For any given set of loading and material conditions a certain minimum of cover thickness must be used regardless of the length of the conveyor. It is easy to visualize that a $\frac{1}{32}$-in.-thick cover on a belt carcass would quickly be cut to pieces by sharp heavy rocks even if any point in the belt came under the loading chute only once every 15 min. A certain amount of cover wear occurs as the load moves along with the belt owing to slight shifting of such load as it goes over each carrying idler.

The lowest quality should be considered only where operating conditions are very easy, as when grain, powdered material, or very small pieces are being conveyed, or in package service. Medium and medium-heavy service conditions can usually be belted with the middle-quality belting. The top quality is indicated only in a few very severe operating conditions. A thick medium-quality cover will do a better job in service than a thin top quality.

Table 20-6. Conveyor-belt Brand Comparison

Company	No. 1 construction, 3,500 lb cover, 20 lb friction	No. 2 construction, 2,500 lb cover, 16 lb friction	No. 3 construction, 800 lb cover, 12 lb friction
B. F. Goodrich	Super Longlife	Longlife	Maxecon
U. S. Rubber	Matchless	Giant	Security
Goodyear	Stacker	Style M	Style W
Manhattan	Super Master	Master	Delhi
Hewitt	Maltese Cross	Ajax	Conservo
Boston Woven Hose	Bull Dog	Silver King	Iron Clad

NOTE: Many special constructions are available for extra-high-tension service. Goodrich and Goodyear make steel-cable carcass belts; U. S. Rubber makes an "Ustex" construction; Goodrich and Goodyear make cotton cord constructions; Manhattan makes what is called a "Homocord" belt; and several companies are experimenting with rayon, nylon, and other special fibers for the tension members in their high-tension belt constructions. Hewitt has made several "Raynile" belts.

Table 20-7 is a guide for thickness of top cover to use for various types of material.

Table 20-7. Thickness of Top Cover

Service	Top-cover gauge, in.	Type of material
Light	$\frac{3}{32}$-$\frac{1}{8}$	Nonabrasive materials such as wood chips, flue dust, loose cement, bone char
Ordinary or standard	$\frac{3}{16}$	Mildly abrasive materials such as sand, small pebbles, earth, or bituminous coal; rock, stone, or coal under 3 in.
Average severe	$\frac{1}{4}$	Abrasive materials such as anthracite coal, coke, and sinter; rock, stone, or coal up to 10 in.
Severe	$\frac{5}{16}$	Heavy abrasive materials such as ores of iron, copper, zinc, and lead; foundry refuse, limestone, and slag
Very severe	$\frac{3}{8}$	Heavy, sharp, abrasive materials such as trap rock, quartz, glass cullet, and iron pyrites, and exceptionally large lumps of any material

Except for the lowest quality belting and for very light service, it is good practice to include in the top-cover thickness either a regular breaker fabric ply or a transcord breaker ply. This not only greatly increases the adhesion of the cover to the belting, but it also assists, particularly in the case of the transcord breaker, in helping to distribute the shock of impact at the loading point over a greater cover area. Table 20-8 is a guide to its use.

Table 20-8

Cover gauge, in.	*Breakers*
$\frac{3}{32}$, $\frac{1}{8}$, or $\frac{3}{16}$	Regular leno breaker included
$\frac{1}{4}$, $\frac{5}{16}$	Include one transcord breaker next to carcass
$\frac{3}{8}$	Include one transcord breaker next to carcass and one floated $\frac{1}{16}$ in. below top surface of the belting

Back-cover Thickness

For light service and low-quality belting, $\frac{1}{32}$-in. back cover is used. For most other service conditions a $\frac{1}{16}$-in. back cover is used. This is especially true when vulcanized splices are used to make the belting endless, as it increases the life expectancy of the splices. For sticky conditions, or where belting may freeze to the idlers or the pulleys, or where the back cover is subjected to a lot of wear or abuse, $\frac{3}{32}$-in. back cover, including regular breaker, or heavier cover is indicated. For very severe conditions, especially where large lumps are handled and the belting is subjected to heavy impact, it is desirable to use a transcord breaker in the back cover.

NOTE: Regular breaker displaces $\frac{1}{32}$ in. of cover thickness, and the minimum cover thickness in which it can be included is $\frac{3}{32}$ in. The transcord breaker displaces $\frac{1}{16}$ in. of cover thickness, and the minimum cover thickness in which it can be included is $\frac{1}{4}$ in. However, while the breaker actually displaces that amount of cover, it is still mainly rubber and does not materially decrease the wear resistance of the cover by its over-all thickness.

EQUIPMENT OVER WHICH THE BELTING MUST OPERATE

Space does not permit a detailed discussion of this part of the conveyor problem. Certain points will be stressed since they govern to a large extent the satisfactory performance of the belting. A number of belt users fail to realize that the belting on the conveyor represents from 40 to 60 per cent of the initial cost of the conveyor installation and also that the belting usually requires replacement before any of the equipment over which it operates.

Types of Drives

There are three types of drives in common use:

1. **Plain Drive.** The plain drive can be either at the head or tail pulley and gives only a 180-deg arc of contact between the belt and the driving pulley.

2. **Snubbed Drive.** On the snubbed drive a snub pulley smaller than the driving pulley is installed to increase the arc of contact between the belt and the driving pulley. The degree of contact can be varied from 210 to a maximum of 260 deg provided the drive pulley is sufficiently large.

3. **Two-pulley Drive.** The common two-pulley drive is known as the tandem drive. Both pulleys are driven from one motor, and the two pulleys are geared together so that they both turn at the same number of rpm. A new drive involving two pulleys is known as the dual-motor drive where each pulley is driven by a separate motor. The motors can be so designed that the speed of the two pulleys will automatically compensate for changing belt length on the pulleys, commonly referred to as "creep."

The purpose of increasing the wrap between the belt and the pulley is to permit the belting to transmit the required horsepower with less initial tension, which results in less total tension in the belting when it is operating under load.

Types of Starting for Conveyor Drives

1. **Across the Line.** Owing to the fact that conveyors often have to be started fully loaded, it is necessary that motors with a high starting torque be used. This

type of starting is the hardest on the belting but can be used on conveyors that are lightly stressed.

2. Autotransformer Starting. In autotransformer starting a lower voltage is fed to the motor for a few seconds until the motor starts to turn over. Then the full voltage is applied to bring the motor up to speed. This is somewhat easier on the belting than the across-the-line type.

3. Resistance Type through a Number of Starting Points. The resistance type can be manually operated or automatic. This type permits a longer acceleration period which, if properly designed, reduces the starting stress on the belting. All belts that are started frequently and are stressed to their full rated strength should have this type of starting or a modified version of it.

4. The Use of a Fluid Coupling. The fluid coupling can be used on the drive shaft of the motor in conjunction with some form of types 2 or 3 starting.

Pulleys, Bearings, and Idlers

Pulleys. Pulley diameters should not be skimped on because of limited headroom unless it is absolutely necessary. Theoretically, it is the amount of wrap between belt and pulley that determines the amount of power which can be delivered before belt slippage occurs, and not the area in contact between belt and pulley. Theoretically, as much wrap can be obtained between a belt and a small pulley as between it and a large pulley. But the stiffness of the belting makes a difference in favor of the larger pulley. It also stands to reason that the plies in a belt are being distorted as they bend over a pulley, the outer plies being stretched and the inner ones put under compression. The amount of distortion increases with the thickness of the belting; increasing the pulley diameter permits this deformation to take place over a longer length. Naturally the higher the working stress in the belting at the time the distortion is taking place, the more damage to the belting. Such severe flexing usually shows up first in short splice life, particularly when the metal type of splice is used.

At the points in an installation where the belting is fully stressed, flat-faced rather than crowned pulley surfaces should be used so that the load in the belting can be equally distributed across the full width of the belting. It is emphasized that the drive, head, and tripper pulleys should all be of the same diameter because they are all working under the same belt stress. It has always been common practice to make the head and tripper pulleys smaller than the drive pulleys in a conveyor that uses a drive which is separate from the head pulley and which may or may not be equipped with a tripper (see Table 20-9 for minimum pulley diameters).

Bearings. On long center, horizontal, or inclined conveyors, it is good design to use either ball or roller bearings on all pulley shafts.

Idlers. It is suggested that consideration be given to the use of larger diameter idler rolls. The larger rolls permit lower rpm with resultant longer bearing life and are somewhat easier on the belt owing to having a greater moment arm for turning. They also give smoother movement of load with less load shifting from slight belt sag. Roll diameter of at least 6 in. should be used, and some of the better conveyor systems have proved the economy of 7- and 8-in.-diameter rolls on large heavily loaded conveyor systems.

The use of three pulley-type carrying idlers with all three rolls the same length and the two troughed rolls placed at 20-deg angle to the horizontal is almost universally accepted practice. There is a trend toward the use of the same design except that the center roll is made about a third longer and the troughing rolls proportionately shorter but still at the same degree of troughing. It has been proved that such an idler will carry about 5 per cent more load without spilling, will give a straighter running belt (because of better belt troughing possibilities), and will give longer belt life because of less concentrated bending of the belting at the junction of the horizontal and troughing rolls.

Idler Spacing. Because belt sag between idlers is a function of the load per foot of belting, the tension in the belting, and the distance between idlers, much better support can be given to the belting by varying the idler spacing. At the point of lowest belt tension (usually the tail end of the conveyor), the idlers should be placed close together, and at the point of high belt tension they should be placed farther apart. The total number used will be the same as though they were uniformly spaced for the entire length of the conveyor.

Recommended Pulley Diameters. Table 20-9 lists minimum pulley diameters for installations where the belt is designed for the plies to take the maximum fabric stresses as given in Table 20-4 If it is certain that the belt will never be stressed above 70 to 80 per cent of its maximum, then the minimum pulley diameters may be taken at tabulated value minus 6 0 in.

Table 20-9. Minimum Pulley Diameters, In.

No of plies	Drive, head or tripper pulley	Tail take-up or high tension snub	Bend pulley or low-tension snub	Drive head or tripper pulley	Tail, take up or high-tension snub	Bend pulley or low-tension snub
	28 oz			32 oz

NOTE Use the following standard pulley diameters if at all possible 12, 18, 24, 30, 36, 42, 48, 54, 60, 72 84, and 96

Take-ups for Conveyors

There are two types of take-ups for conveyors in common use:

1. **Screw.** The screw type of take-up moves the head, tail, or take-up pulley and positively fixes the centers. It is usually used on short-center conveyors and necessitates higher stresses in the belting than are actually necessary for belt operation.

2. **Gravity.** The gravity type of take-up keeps a constant tension in the belt and

is free to come and go with change in belt length. The head or tail pulley can be mounted on a movable carriage with a cable and weights attached to the carriage, or the belt slack side may be led over two bend pulleys with a weighted pulley suspended between.

Advantages of a Take-up of the Gravity Type. 1. A take-up of the gravity type maintains a constant T_2 tension necessary for the drive to operate the belt without excess slipping occurring.

2. It helps to keep belt sag between idlers at a minimum, particularly at the point of low belt tension, thus preventing load disturbance and saving power.

3. Permits belt-length change due to stretch or shrinkage and at the same time keeps the tension in the belt constant.

4. Takes care of the instantaneous belt stretch which occurs when the belt is started and maintains belt tension.

5. Particularly if vulcanized splices are used, it is well to provide take-up movement equal to 2 to 3 per cent of the center distance between head and tail pulleys. This will provide ample movement to accommodate any shrinkage or stretch that may occur. It will provide plenty of movement for the instantaneous stretch which occurs when belt is started, and it will provide storage space for spare belting in case of damage to the belt. It also provides extra belting for splice replacement if needed.

Calculating Take-up Weight. Care should be used in estimating the amount of take-up weight needed for any particular conveyor design. The take-up weight is equal to the sum of the component forces in the direction of belt tensions at the take-up pulley, wherever its location may be. The point of location is very important also. For horizontal conveyors, it is usually best to have the take-up located as near to the drive as possible and in the slack side of the belt. For inclined conveyors it is usually best to have the take-up at the tail pulley for uphill conveyors and at the head pulley for downhill conveyors.

There is another factor to be considered in calculating take-up weight. That factor is the idler retarding force on the return strand of belting, and it is equal to $F_R = 0.4(G \times F_x \times L_r)$. Space does not permit explanation regarding how to figure take-up weight for each of the examples given by Figs. 20-18 to 20-26, inclusive.

Vertical Curves

Vertical curves refer to the radius of curvature necessary on those conveyors which change from the horizontal or from a given degree of incline to a steeper degree. Frequently too small a radius is used with the result that the belt under tension raises from the idlers and damages itself or spills its load. It is much better to be sure and use a large radius. This is especially true when dealing with high-tension belts such as the No. 70, No. 100, and the five steel-cable cord constructions.

Table 20-10. Recommended Maximum Belt Speeds, Fpm, for Horizontal and Elevating Conveyors

Material to be conveyed	Belt widths, in								
	12	18	24	30	36	42	48	54	60
Light, free-flowing material	300	400	500	600	600	600	700	700	700
Coal and similar lump material	300	400	500	550	550	600	600	650	650
Heavy ore and abrasive material	300	350	450	550	550	550	600	600	600

The most efficient conveyor-belt operation is usually with the narrowest belt at the highest speed at which good loading is obtained and without doing any damage to the material. Increasing the belt speed without changing the rate of loading tends to lower the necessary belt tension. This is sometimes done on long-center conveyors to decrease the stresses.

Table 20-11

Slope angle of declining conveyor at loading point, deg	*Recommended maximum belt speed, fpm*
7 or less	90% of value in Table 20-10
8-14	75% of value in Table 20-10
15 and above	50% of value in Table 20-10

Cubic feet per hour for each 100 fpm belt speed = 6,000 × load cross section in square feet.

Especially with light free-flowing material the factor determining the maximum speed is the windage which may blow the material from the belt. The average speed of grain belts is 800 to 1,000 fpm, with some operating up to 1,200 fpm.

The type of chute or mechanical feeder will often determine the speed at which a belt may operate satisfactorily. If the carrying-idler spacing is graduated and the belt tension is maintained correctly so that the load travels smoothly, higher speeds are often possible. If it is necessary to load onto a belt where it is at a slope angle of 10 deg or more, slower belt speed may be necessary to get full-capacity loading.

When declining conveyors are considered, the amount of slope at the loading point is usually the determining factor as far as maximum belt speeds are concerned. If the loading point is on a horizontal run, the belt speed for the declining conveyor can be as high as that shown in Table 20-10. Keeping full rated load on the belt for its width and speed helps downhill operation.

Where it is necessary that the loading of a downhill conveyor be on the slope, lower speeds than specified in Table 20-10 are recommended. These are shown in Table 20-11.

The capacity at any belt speed and with any weight of material can be found by using the constants shown in Table 20-13.

Table 20-13

Belt width, in.	*Capacity in short tons (2,000 lb) per hr*
12	0.00286 × fpm × wt per cu ft of material, lb
18	0.0068 × fpm × wt per cu ft of material, lb
24	0.0125 × fpm × wt per cu ft of material, lb
30	0.0200 × fpm × wt per cu ft of material, lb
26	0.0290 × fpm × wt per cu ft of material, lb
42	0.0406 × fpm × wt per cu ft of material, lb
48	0.0550 × fpm × wt per cu ft of material, lb
54	0.0715 × fpm × wt per cu ft of material, lb
60	0.090 × fpm × wt per cu ft of material, lb

NOTE: The capacity values given are obtained with standard 20-deg troughing idlers. Consider flat conveyor belts as giving one-half the capacities shown.

Table 20-14. Size of Maximum Lumps

Belt width, in.	Max lump size, in.	
	Uniform size	If mixed with 90 % fines
12	2	4
18	4	6
24	5	8
30	6	10
36	7	12
42	8	14
48	10	16
54	11	20
60	12	24

With a heavy belt, very close idler spacing, and skirt boards the entire length, much larger lumps have been carried than shown in Table 20-14. In some cases material has been carried where all three dimensions are equal to the belt width, but this is detrimental to belt and idlers.

There are a number of other considerations which may affect the slope angle. If slope is over 16 deg, if belt is running too fast, or if it is only partially loaded, there is danger of lumps falling back down the slope. This is liable to be a hazard for the belting, equipment, and workmen. In several cases, swinging bars with a stop against the downslope side have been used. The bars swing forward to let the load pass through but if lumps start rolling back, the bars are held against the stop and the backward flow of material is dammed. Several of these swinging bar units are used on a

Table 20-15. Approximate Unit Weights of Various Materials

Materials	Weight, lb per cu ft
Minerals	
Coal, anthracite (broken and loose)	55
Coal, bituminous (broken and loose)	45
Ashes of bituminous coal	35–45
Ashes (damp)	40–50
Cinders (coal and ash)	40–45
Cinders (blast furnace)	57
Coke (loose)	23–32

Grain		
Wheat	48	60
Barley	38	48
Shelled corn	45	56
Flour	56	70
Oats	26	32
Rye	45	56

NOTE One bushel equals 1.244 cu ft The solid or compact weights of the various materials cannot be used in considering the capacity of a conveyor belt because the belt usually carries crushed material. A close approximation of the crushed weight of an ore or rock equals solid weight divided by 1.75. All the weights in Table 20-15 are for crushed material as would be carried by a conveyor belt except those specified as being for a solid. Wherever possible, the actual material weight as determined by test should be used

Table 20-16. Maximum Incline Angles

Material handled	*Max angle, deg*
Dry silica sand	15
Paper-wrapped packages with flat surfaces on belting with standard canvas or rubber cover	16
Free-flowing materials such as washed gravel, fine-sized coal, grain, etc	18
Size lump materials such as stone, lump coal, ore, etc., of less than ½-in. size	22
Granular materials such as sand, glass batch, or salt	22
Powdered materials such as lime, cement, sulfur, chemicals, etc	23
Mixtures of lumps and fines such as run-of-mine coal, crushed stone, etc	24
Tempered molding sand	24
Wood chips	27
Paper-wrapped packages with flat surfaces and soft bagged material or special "grip-top" belting	28

slope. If material is wet and sloppy, the angles shown in Table 20-16 must be decreased. If there is slip between material and belt, excess wear will occur at belt-cover gouges and fasteners.

TRIPPER HORSEPOWER AND REDUCTION-DRIVE LOSSES

Tripper Horsepower. As stated on page 1421, the horsepower necessary for tripper operation must be included with the $x + y + z$ horsepower factors to get total power necessary to be transmitted to the belt.

The horsepower necessary to lift the load at the tripper should be included in the lift-horsepower calculation for the conveyor. Therefore, when tripper is used, its lift in feet should be included in the H value in the Z formula. If exact lift at tripper is not known, add 4, 5, 6, 7, or 8 ft, depending on belt plies which are estimated to be necessary.

Table 20-17. Value of *G*

Belt width, in.	*G*		
	Light conveyors	Standard conveyors	Heavy-duty conveyors
14	9	14	
16	10	16	
18	11	17	
20	12	19	
24	15	22	32
30	18	26	45
36	21	32	58
42	24	45	71
48	29	52	84
54	35	61	97
60	38	71	110

If the value of *G* is to be calculated, belt, idler, and pulley weights must be known.

To compensate for the added moving parts when tripper is used, increase the G value by 5 per cent.

Therefore, if tripper is to be used and a 30-in. belt on heavy-duty conveyor is being considered, the H and G values might be increased as follows:

H should include 6 ft of tripper lift. Increase G by 5 per cent, or from 45 to 47.3.

If G, Table 20-17, is being calculated, then the weight of tripper pulleys should be included to get the correct value.

Horsepower for Drive Losses. *Type of Reduction Units.* For cast-tooth gears, add 10 per cent for each reduction.

For cut-tooth gears, belting, or roller chain, add 5 per cent for each reduction.

For self-contained spur- or helical-gear reducers, add 5 per cent for each reduction.

Considering an average reduction to be a gear-reducer and roller-chain combination and 320 hp calculated to be necessary to drive loaded belt at drive pulley or pulleys, then

$$320 \times (5\% + 5\%) = 320 \times 10\%, \text{ or } 32 \text{ horsepower}$$
$$\text{Estimated motor output or rating} = 320 + 32, \text{ or } 352 \text{ hp}$$

A motor and also gear, chain, or belt reductions are most efficient at their rated loads. The motor and reduction units should be chosen so that they will be operating as nearly as possible to full-load rating.

G (Weight of Moving Parts)

G may be taken from Table 20-17 if it is not convenient or possible to calculate. For large installations, it is best to obtain the details and calculate.

Calculation of G. Since G equals the weight of moving parts per foot of conveyor centers, its value may be calculated easily by taking the sum of the following four factors:

1. Total weight of the entire length of belting used. The entire belting length equals approximately twice the conveyor center length.
2. Total weight of pulleys which are turned by the belt.
3. Total weight of moving parts of all troughing idlers.
4. Total weight of moving parts of all return idlers.

Then divide this sum by the length of conveyor centers as measured along the belt.

Belt Weights. Weights (Table 20-18) are given on three grades of belting specified as first, second, and third quality. First quality are reserved for the very severest of service, and the weights are based on compounds made from natural crude rubber. Second grade are for average-severe service and third grade for medium or light duty.

Table 20-18

Duck weight, 42 in. wide × 36 in. long	Grade	Belt weights, approx net weight lb per in. width per ft length

Steel cord, No. 3000*	First	0.505 for carcass per in. of belt width 0.017 per $\frac{1}{32}$ in. of cover

* These constructions are made by the B. F. Goodrich Company. For special constructions made by other manufacturers it will be necessary to get the correct belt weight from the manufacturer.

The approximate weights of terminal, snub, or drive pulleys are given in Table 20-19.

For any important installations where an exact value of G should be used, obtain the exact weight of moving parts from the equipment manufacturer.

F (Coefficient of Rotational Friction of Pulleys and Idlers)

Tests of actual conveyor systems have indicated that the greatest accuracy can be obtained in the horsepower calculation by using two values of F. One value should

Table 20-19. Pulley Weights

Pulley diameter, in.	To calculate approx pulley weight, lb	
	Cast-iron pulleys	Welded-steel pulleys
12	7 lb × face width, in.	3 lb × face width, in.
18	11 lb × face width, in.	6 lb × face width, in.
24	16 lb × face width, in.	10 lb × face width, in.
30	22 lb × face width, in.	13 lb × face width, in.
36	29 lb × face width, in.	17 lb × face width, in.
42	37 lb × face width, in.	
48	46 lb × face width, in.	
54	56 lb × face width, in.	
60	75 lb × face width, in.	
72	98 lb × face width, in.	
84	120 lb × face width, in.	
96	142 lb × face width, in.	

These values are approximate pulley weights. Use the pulley manufacturers' value of weight whenever available.

Table 20-20. Weight of Idler Moving Parts

55	..	..	78	163	..		65	134
60	..	..	86	174	..	.	71	147

Special heavy-duty types of steel troughing idlers may weigh 30 per cent over the above figures and cast-iron idlers will weigh approximately 60 per cent more than above.

be used for calculating the horsepower necessary to drive the empty belt, and a slightly larger value of F gives greater accuracy for figuring the horsepower to carry the load horizontally.

Values given in Table 20-21 for the most ideal condition should *rarely be used.* Horsepowers calculated with F_x and F_y of 0.025 and 0.030 have seldom been attained in actual service. There are only one or two cases where this was accomplished, owing to

1. Highest grade antifriction idlers used
2. Graduated spacing for troughing idlers
3. All terminal and bend or snub pulleys mounted with antifriction bearings
4. Experiments made to determine belt tension necessary for least horsepower
5. Very superior maintenance practiced

Cold-weather operation tends to raise the coefficient of friction slightly. Tests have indicated that for 20°F operation the coefficient-of-friction values should be raised approximately 10 per cent. This increase has very little effect on the horsepower necessary for a conveyor unit which has most of its need of power in elevating

Table 20-21. Values for F

Type of bearing and condition of conveyor	F_x	F_y
Most ideal	0.025	0.030
High grade	0.030	0.040
Average to be used if no details known except that antifriction idlers are used	0.035	0.050
Plain bearing	0.050	0.075

the load. The effect is greater on long horizontal installations where most of the total power is for moving the empty belt and carrying the load horizontally.

Actual field tests have indicated slightly lower coefficients of rotational friction than most of the values in Table 20-21. However, owing to the many variables of equipment maintenance, operating temperatures, etc., Table 20-21 values are slightly on the safe side.

Table 20-22

Angle of belt wrap at drive, deg	Type of drive	Drive factor K*			
		Screw take-up		Gravity-weighted or flexible take-up	
		Bare pulley	Lagged pulley	Bare pulley	Lagged pulley
180	Plain	1.6	1.0	0.84	0.5
190	Snubbed	1.5	0.9	0.77	0.45
200	Snubbed	1.4	0.8	0.72	0.42
210	Snubbed	1.3	0.7	0.67	0.38
220	Snubbed	1.2	0.6	0.62	0.35
230	Snubbed	1.2	0.6	0.58	0.32

400	Tandem	†	†	0.21	0.095
420	Tandem	†	†	0.19	0.084
440	Tandem	†	†	0.17	0.074
460	Tandem	†	†	0.15	0.064
480	Tandem	†	†	0.14	0.056

* The drive-factor constant multiplied by effective tension T_E equals slack-side tension T_2.

† Not recommended.

NOTE: A 210 deg arc of contact on snubbed-head pulley drives and a 420 deg arc of contact on tandem or dual-motor drives are most frequently used. Belt wraps above 220 deg are not recommended for use with screw take-up but must be used in some cases for underground service. The trend is toward the use of snubbed-head pulley drives with 240 deg arc of contact on long-slope conveyors where a high belt-slope tension exists.

Then for plain, snubbed, or tandem drives

$$T_E = (\text{hp} \times 33{,}000)/S$$
$$T_2 = KT_E$$
$$T_1 = T_E + T_2 = (K + 1)T_E$$

With reference to the maximum plies as indicated in Table 20-23, a greater number than nine plies of 28- or 32-oz duck would trough in the 48-, 54-, or 60-in. belt widths, but if more than nine plies are needed, a heavier weight of duck should be used. Likewise, 10 plies in the 36- and 42-oz constructions should be considered maximum for good balance. More than 10 plies would trough in the 42-, 48-, 54-, and 60-in. widths with the cord constructions, but consider 10 plies as the maximum to be used. The steel-cord belts will trough well in all widths of 24 in. and over. Probably 24 in. will be the minimum width for use of steel cord.

FREIGHT ELEVATORS

BY E. M. BOUTON

Manager of Engineering, Elevator Division, Westinghouse Electric Corporation

INTRODUCTION

Freight elevators are used for handling material in many different types of buildings, such as factories, warehouses, and department stores, in fact, in every type of building where material must be moved from one floor to another. The kind of material handled and the manner in which it is packaged and moved on and off the elevator vary greatly, as do the amount of material to be handled and the frequency of the service which is required. In general, as compared with passenger elevators, freight elevators handle much heavier loads, but the speed required of the car is not so great, owing largely to the fact that the loading and unloading is such a large percentage of the total cycle. The usual range of capacity of freight elevators is from 2,500 to 20,000 lb, although in special cases even larger capacities are required.

Speeds used vary from 50 to 200 fpm for most applications, although here, also, are found occasional requirements for speeds up as high as 500 fpm.

The appointments of the freight-elevator cars are much simpler than passenger elevators, there being no particular requirements for ornamentation. Ruggedness and safety are the most essential characteristics.

At the present time practically all freight elevators are of the electric type, although there are a few low-rise applications where the hydraulic lift may be employed to good advantage. Such cases are limited to a very low rise, not over 25 ft, and where the speed can be very low, usually not over 35 fpm.

Material handling in modern manufacturing operations has, in recent years, been receiving increasing attention. An analysis of manufacturing costs shows that the cost of moving material is one of the largest single elements in cost analysis. In the past much attention has been given to speeding up machining operations involving the use of high-speed steel so that cost of cutting operations has been greatly reduced. The use of spraying with special spray guns combined with conveyors has greatly reduced the cost of applying paint and finishes.

It is only recently, however, that the cost of moving material from one position to another has received serious consideration. During the Second World War, however, great impetus was given to the methods of material handling, resulting in increased use of power trucks and palletizing of material. The freight elevator must be considered one of the elements of a material-handling system, and many of the recent developments in material handling have definitely affected the design of freight elevators and have imposed new requirements which must be met by this equipment. Fortunately, considerable development has taken place in freight elevators and modern industrial freight elevators, if properly applied, will in many cases contribute greatly to the efficiency of the material-handling problems of a manufacturing plant.

ELEVATOR MACHINES

The *traction machine* came into use about 1900 and today has practically replaced the drum machine except for a few specialized applications. In the drum machine the hoisting ropes, or cables, used for hoisting the car are wound up on a drum, one end of the ropes being attached to the car and the other attached solidly to the drum. These machines have a number of serious limitations which the traction machine does not have. In the traction machine the ropes are attached to the car and pass over the machine sheave, or drum, the opposite end of the rope being attached to the counterweight. The car is driven by the friction, or traction, between the rope and the sheave. The traction machine is the safest type that has ever been evolved in that any danger of overwinding has been entirely removed. Should the car overtravel at the top, the counterweights will rest on the bottom of the pit, traction will be lost, and overwinding thus prevented. The traction machine has great flexibility in that the same sheave may be used for any height of building. Traction machines may be either geared or gearless. In the gearless machine the driving sheave is mounted directly on the motor shaft, the rpm of the sheave being the same as that of the motor armature. This type of machine is the one most suitable for high-speed passenger elevators but is used for freight elevators only in special applications. Where heavy loads are to be lifted, the high torque requirements of the motor make it prohibitive in cost so that for freight elevators the geared-type machine is used. Figure 20-27 illustrates a geared traction machine of the type that is most generally used for freight elevators. In this machine the gear is mounted on the drum shaft, and the drum shaft with its gear and drum are supported by heavy roller bearings. Since the entire weight of the car, counterweights, and load is supported by this shaft, these bearings are made extremely rugged. This gear meshes with the worm, the worm shaft being coupled directly to the motor shaft. The thrust developed by the gear is taken by substantial thrust bearing on the end of the worm shaft. In this machine the motor is flange mounted to the machine housing, which eliminated any problem of alignment of the motor shaft and the worm shaft. The essential characteristics of this machine are simplicity and ruggedness, making it well adapted to the requirements of freight elevators in modern industrial plants.

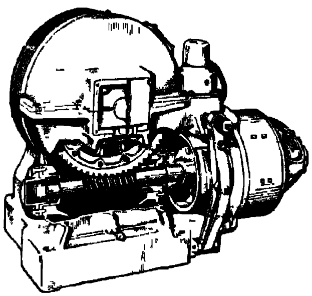

FIG. 20-27. Worm-geared traction elevator machine.

The methods of roping used with traction elevators are 1:1 (see Fig. 20-28), 2:1 (see Fig. 20-29), and 3:1 (see Fig. 20-30).

It is the usual practice to make the counterweight equal to the weight of the car plus approximately 40 per cent of the rated load in the car. Where the rise is more than 100 ft, it is the usual practice to hang compensating ropes from the bottom of the car to the bottom of the counterweight so that the weight of the car does not change appreciably at different positions in the shaft.

Roping with a 1:1 ratio is very generally used for passenger elevators where the load is comparatively light and the speed high. It is also used for freight elevators, but in this case the torque required by the drum shaft becomes very high for heavy loads, and a double reduction gear is required. This involves the introduction of spur gearing between the worm wheel and the sheave and complicates the design of the elevator machine. In order to use the simple worm-gear machine, 2:1 roping is very extensively used for heavy industrial freight elevators. With 2:1 roping the car speed is one-half the rope speed, but the load that can be lifted for a given pull on the rope is twice as great as 1:1 roping. Roping with a 3:1 ratio is occasionally used where very heavy loads must be lifted and the speed is low.

Traction drives may be further classified as single wrap and double wrap. The double-wrap traction is illustrated in Fig. 20-31 and has the same general characteristics as the single wrap shown in Fig. 20-28, but in this case an additional wrap is made about the driving sheave, thus increasing the traction for driving. It also doubles the load in the sheave bearings. The sheave groove in this case is known as U grooving, as illustrated in Fig. 20-31. This system is useful for high-speed freight elevators using a gearless machine. For freight elevators the single-wrap traction is generally used, in which case the grooves have an undercut, as shown in Fig. 20-28. This particular shape of groove gives high traction and good support for the rope.

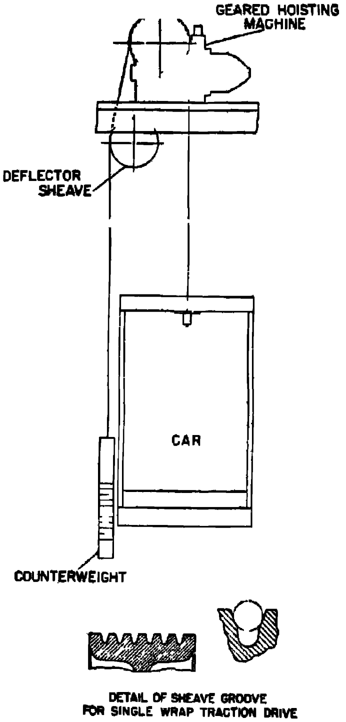

Fig. 20-28 Single-wrap traction elevator with 1:1 roping showing detail of sheave groove

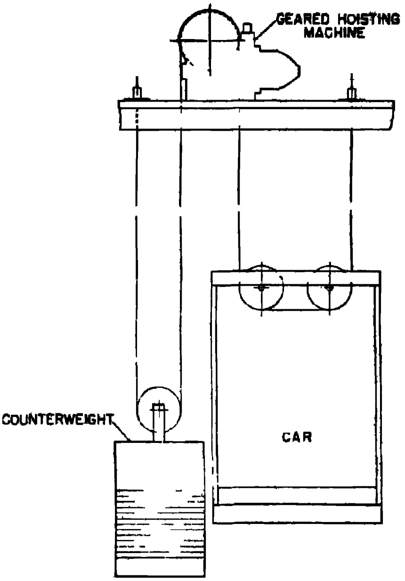

Fig. 20-29 Single-wrap traction elevator with 2:1 roping (Sheave grooves same as Fig. 20-28.)

Furthermore, the traction does not change as grooves wear, thus ensuring a long life of both sheave and rope.

The car is hoisted by means of wire rope. Elevator hoisting rope is a rather complicated structure, composed of a number of strands of wire which are wound upon a hemp center. The hemp center forms a support for the strands and carries a lubricant. The various strands must move freely with respect to one another to prevent internal wear. In order to obtain a satisfactory rope life, the ratio of sheave diameter to rope diameter should be kept as high as practicable. The American Standard Safety Code requires that the sheaves be at least 40 times the rope diameter. In practice, a ratio of 50:1 or more is usually used. Wire rope is manufactured in a number of constructions. For traction elevators it is desirable to have the outside wires in the strand large in order to prevent breakage due to wear from contact with the driving sheave.

MOTORS AND CONTROL

Both a-c and d-c motors are used for elevator service. The simplest and most rugged type of motor is the single-speed squirrel-cage motor with high starting characteristics. Such motors are designed to give the maximum torque at starting. To obtain the high starting torque, a high rotor resistance is required so that the motor has considerable slip, and its speed regulation is not so good as that of the d-c motor. It is started by connecting it directly to the line, usually with a step or two of primary resistance, and is stopped by disconnecting it and bringing the car to rest by the friction brake on the elevator machine. No speed control can be obtained so that this type of motor is limited to low-speed elevators, 75 to 100 fpm, and where accurate stopping is not important and where self-leveling is not required. A modification of this motor is known as the two-speed motor, in which the motor has two sets of poles, thus giving two speeds, or has the primary reconnected on slowdown so as to change the number of poles. The starting characteristics of such a motor must be the same as for a single-speed motor, but by utilizing the greater number of poles the slower speed is available for stopping. Such motors have been built with pole changers with 6:1, 4:1 and 3:1 speed ratios and with reconnected primary with a 2:1 speed ratio. Such motors have been extensively used in the past as a means of obtaining higher car speeds or to obtain more accurate landing. In recent years, however, the development of variable-voltage control in smaller ratings gives much better performance, more accurate control, so that the use of two-speed a-c equipment has greatly decreased. Variable-voltage equipment may now be obtained in ratings as low as 10 hp so that there is very little need for an a-c motor for car speeds above 100 fpm.

In *variable-voltage* control a d-c elevator motor is used, and the speed and direction of rotation of the motor are obtained by controlling the field of a generator. In this case, there is a motor-generator set for each elevator. The generator may be driven by either an a-c or d-c motor, most of the drives being alternating current. The motor and generator are combined in one unit, or motor-generator set, which also includes an exciter. For speeds up to 200 fpm, which are usual for freight elevators, a compound-wound generator is used, compounding being obtained by a series field on the generator used for the purpose of compensating for load and giving good speed regulations both at high and low speed. The great advantage of variable-voltage control for any kind of elevator service is the smoothness with which the elevator operates and the accurate speed control which can be used for making landings. This good speed control is particularly necessary where automatic self-leveling is required, in that the car must be moved at a very low speed so as to obtain the required stopping accuracy.

Variable voltage is recommended for all freight elevators above 100 fpm and for lower speeds with 10,000 lb capacity or greater.

The control operating systems used for freight elevators are as follows:

1. Collective
2. Push button (single party)
3. Car-switch control
4. Constant-pressure push button

The system that is the most serviceable and best adapted to freight-elevator service is collective operation. With this system there are UP and DOWN buttons in the corridor on each floor and a set of buttons in the car corresponding to the floors. The car is started in response to the pressure of these buttons. With selective collective operation, which is the system most generally used, the car on its up trip responds only to up calls in the corridor and on the down trip responds only to down calls in the corridor. As it travels through the hoistway, it automatically stops for the calls received and in the natural order of the floors. All calls are stored so that, after completing a trip in one direction, the car will automatically start and answer all the calls in the other direction in the natural order of the floors served. While making a trip in either direction the car will also stop in response to any buttons that may be pressed within the car. When this system is equipped with an attendant service feature and annunciator in the car, it may be used with an attendant in which case the corridor buttons do not start and stop the car but register signals on the annunciator. The attendant controls the car by means of the car buttons. This system may be equipped with automatic self-leveling so as to maintain the car level with the floor during loading and unloading.

Where the service is less severe, push button operation of the single-party type may be satisfactory. With this system the car may be called to any floor by means of the corridor buttons or sent to any floor by means of buttons in the car. Since it responds to but one call at a time, it is limited to relatively infrequent service.

Car-switch operation is a system in which the car is controlled by a lever in the car and requires an attendant. This system may be equipped with automatic self-leveling. In order to eliminate the need of an attendant, a modification known as constant-pressure push-button operation is sometimes used. It has an UP button and a DOWN button in the car by means of which the car is started and stopped and buttons in the corridor which also control the car. The car is not automatically stopped but stops when the operating button is released. It is therefore necessary, when calling the car from a corridor button, to observe the position of the car through a vision panel to see that it is at the floor level. It is suitable only for slow-speed elevators where the service is not severe.

MECHANICAL EQUIPMENT

The *shaft*, or *hoistway*, in which an elevator runs is a very important element in its safe operation. It forms part of the building structure and contains the guide rails on which both the car and counterweight travel. The enclosing walls and the landing doors should be fire resistant. The building structure itself must furnish the proper support for the elevator and sufficient structure to which to attach the elevator guide rails. This is particularly important for freight elevators where power trucks are run on and off the car and where the car platform is subject to eccentric landing. At the bottom of the shaft, known as the pit, are located the terminal stopping devices, consisting of control limit switches, a governor-rope sheave, and the car buffer.

Car buffers may be either of the spring or oil type. Most elevators below 200 fpm use spring buffers, which covers a large number of freight elevators. For higher speeds an oil buffer is used. Oil buffers are designed to stop the car from governor tripping speed with an average retardation of gravity, and the American Safety Code for Elevators requires that the maximum instantaneous retardation shall not exceed 2½ times gravity.

The most suitable location for the elevator machine is directly above the hoistway, as, in this case, the roping is simpler, and the load on the building structure is less than when the machine is mounted in the basement. The building structure must be designed to support the weight of the loaded car and its counterweights, plus the weight of the machinery when located overhead.

Every elevator is equipped with an undercar safety which grips the guide rails in case of broken hoist ropes or in case of overspeed. This safety is actuated by a speed governor located overhead. There are two classes of safeties generally used:

1. Instantaneous safeties
2. Sliding safeties

Where the car speed does not exceed 100 fpm, the instantaneous, or roller-type, safety is used. In the instantaneous safety a roller is wedged between the safety jaw and the elevator guide rail, and the car is brought to rest with practically no slide. Where the speed exceeds 100 fpm, sliding safeties in a variety of forms are used. A very common type of safety is known as the wedge clamp. When the governor trips, the governor rope is brought to rest, causing a drum on the safety to turn, thereby applying the safety jaws to the rail. An improvement on the wedge-clamp safety is to make the jaws flexible so that the operation of the safety drum compresses a spring in the jaw mechanism, thus giving a uniform braking action which it is possible to adjust to any desirable value.

Every elevator should be equipped with terminal slowdown and stopping switches which will act independently of the operator to slow the car down and bring it safely to rest at the limits of travel.

All elevator doors should be equipped with electric contacts so that the car cannot be moved with the doors open. The doors should also be equipped with locks so designed that they cannot be opened on the outside unless the car is at the floor. Devices in which the lock and the contact are combined in such a way that the car cannot be moved unless the door is both closed and locked are known as interlocks. A device in which the contact can be made while the door is still unlocked, even though the locking mechanism is in a position to lock the door when the car leaves, is known as a contact and lock. American Standard Safety Code for Elevators describes these devices and establishes rules for their design, approval, and use.

APPLICATIONS OF FREIGHT ELEVATORS

In selecting a freight elevator for a factory, warehouse, or other use, a number of factors have to be considered. The requirements vary over a wide range from lightly loaded, infrequently used elevators to heavily loaded industrial elevators which are constantly kept in use in handling materials. The character of the material to be handled is the first consideration, taking into account its shape, density, and its distribution on the elevator platform. The way in which material is brought to the elevator has a great bearing upon the design of the elevator and the type to be used. Consideration must be given to the amount of material to be handled in a given time and the number of floors over which it is to be distributed. From a consideration of these factors, the general type of the elevator, its capacity, its platform size, the speed at which it is to be run, and the operating system and control may be intelligently determined.

The size and shape of the elevator platform must be studied in relation to the material loaded upon it and carried by it. The nature of this material has a great bearing upon the platform size for a given load, and the density of loading in pounds for a square foot vary greatly. A large platform area may be necessary to handle bulky objects even though the weight of these objects is light. On the other hand, the material may be dense, and the loading per square foot very high, as in the case of elevators carrying castings, plate glass, and many forms of palletized material. This great variation in density of materials leads to necessity for careful consideration of the use of the elevator over a long period of time. Large elevator platforms designed for light loading may be severely overloaded and may even become a hazard if their use is changed to carry more dense materials.

One of the most important considerations in selecting or specifying an elevator is the method of loading. This also is related very closely to the general material-handling methods used in the plant in which the elevator is to be installed.

Freight-elevator loading may be classed as follows:

1. Industrial-truck loading
2. Motor-vehicle loading
3. General freight loading
4. Passenger loading

Industrial-truck Loading. A method of material handling that has become very generally used in modern industrial plants and warehouses is that of palletizing material and moving these pallets from place to place with power trucks.

Palletizing came into very general use during the Second World War, and today material is stored on pallets, warehoused, shipped, and sometimes consigned by the pallet load. In factories a form of platform frequently called a skid is often used. These skids may be of the box type and are loaded with bolts and nuts and other hardware. Palletized material is well adapted to stacking in tiers. Stock rooms are frequently arranged to store material on pallets or skids, thus greatly reducing the amount of handling required. The power trucks used to handle these pallets and skids are of the forked type and are powered, usually by storage batteries and in some cases by gasoline motors. These trucks are very heavy, frequently weighing more than the load which they handle. In the usual design of such a truck, the load is balanced by the weight of the operating machinery, storage batteries, etc. Thus when fully loaded, most of the weight of the truck and its load are supported on its two front wheels. This results in a very high concentration of loading, and when elevators are loaded by this means, the platform design must take this into consideration.

A large elevator will handle several truck or pallet loads of material, and the usual practice is to spot these palletized loads on the elevator platform by driving the truck onto the elevator, depositing the load and driving it off again. This process is repeated several times until the elevator is fully loaded. Figure 20–32 is an elevation of a freight elevator being loaded with palletized material by means of a power truck. It will be noted from the figure that, as the truck is driven onto the elevator, the front wheels are resting on the edge of the platform so that the weight of the truck and its load are concentrated at this point. Therefore, an elevator that is to be used with industrial-truck loading must be structurally strong enough to support these heavy loads at a considerable distance from the center of the platform. The arrows in Fig. 20–32 show the direction of the reactions that occur at the elevator guide shoes These reactions represent the forces with which the guide rail resists the moment induced by the load at the edge of this platform. Therefore particular attention must be given not only to the design of the elevator but also of the guide rails and guide shoes. It will also be noted from Fig. 20–32 that, just before the truck rolls onto the platform, it had to pass over the trucking sill which is part of the elevator door. Special consideration must be given to this part of the equipment also, and trucking sills for industrial-truck loading should be specified. Figure 20–33 shows a plan view of a power truck and palletized load as it is being run onto the elevator. It should be noted here that not only are the truck and its load supported on the edge of the platform but they are also considerably off center and concentrated on but one side of the car. This eccentricity of loading sets up reactions at the guide

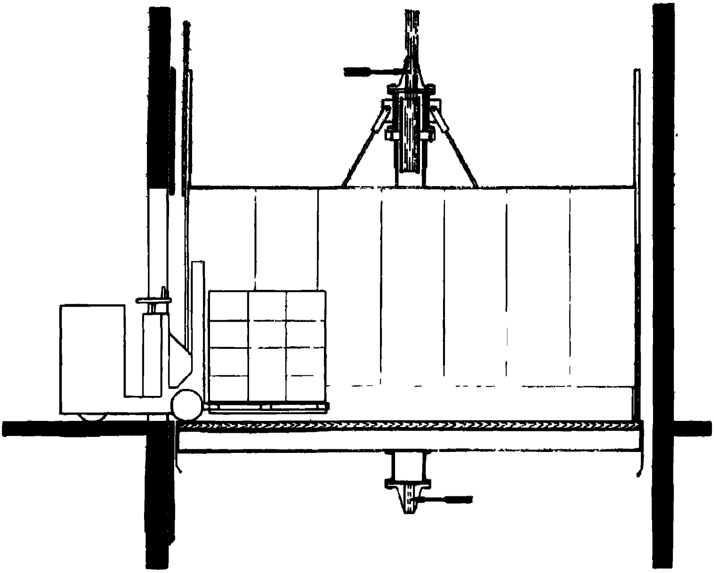

FIG. 20-32. A power truck and its palletized load entering an elevator. Most of the weight of the truck and its load are supported by the front wheels, which rest on the edge of the elevator platform. The arrows indicate the reactions of the guides.

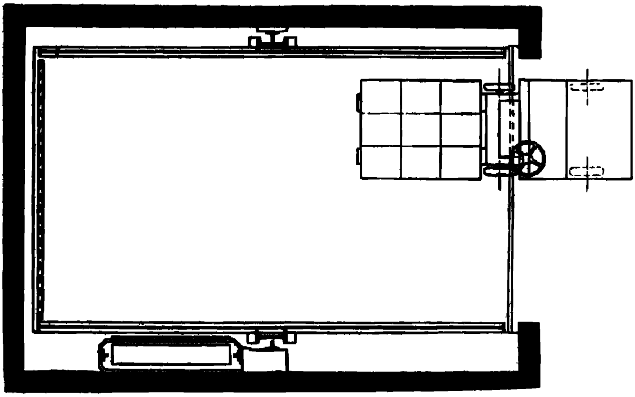

FIG. 20-33. Plan view of a power truck and palletized load entering an elevator. This shows that the load is not only concentrated at the edge of the platform but is displaced sidewise.

rails which are at right angles to those shown in Fig. 20-32 and this too must be given proper consideration.

It is not sufficient that the elevator alone be properly designed for this severe loading. It must be given consideration in the design of the building. Elevator guide rails can be no more rigid than the steel on which they are mounted, and a sufficient number of adequately designed guide-rail supports must be provided.

These modern trucks are operated at considerable speed and must be stopped by means of hand brakes while on the car. This gives rise to inertia force created by stopping the truck. This force must be absorbed by the guide rails and their supports.

Another factor which must be given consideration is the fact that in running these truckloads of material on and off the elevator, perfect accuracy in driving cannot always be expected. It is therefore, not unusual for truck drivers to strike the side of the car with a truck or the load, and elevator side guards must be designed to withstand this treatment. It is not unusual in factories and warehouses, where elevators were not originally designed for power-truck loading, to see the side guards bent and bowed from this cause. A practice which is quite generally followed and which has proved generally successful is to mount wooden rubbing strips on the sides of the car. A very commonly used form of rubbing strip is an oak plank approximately 2 in. thick, bolted to the side of the car. These rubbing strips stiffen the car sides and are readily removable when they eventually become worn.

When palletized material is loaded onto an elevator by means of power trucks, consideration should be given to the total load on the platform. Figure 20-34 shows the palletized load being deposited on the car. In this case the total load on the platform is equal to the total load to be hoisted by the car, plus the weight of the power truck. In many cases the elevator is called upon to hoist not only its load but also the truck by means of which the car is loaded. In this case the total capacity of the elevator must be equal to the weight of the net or payload plus the weight of the power truck.

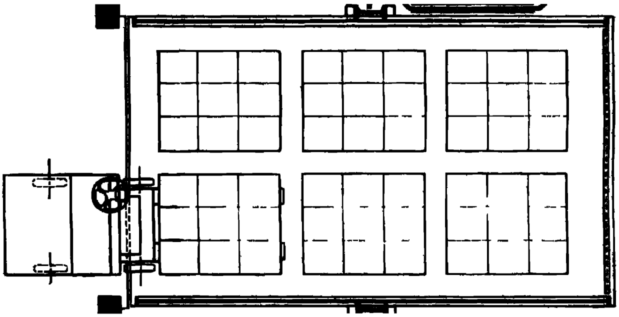

FIG. 20-34. Plan view of a loaded elevator as the last truck load is being deposited on the platform. The total load on the elevator is the weight of the load plus most of the weight of the truck.

Motor-vehicle Loading. In many large warehouses and some industrial plants, it is the practice to drive loaded automobile trucks directly onto the elevator. The truck and its load are then hoisted or lowered to a different level and driven off again. Special consideration must be given to this type of loading, but in general it is less severe than the case of industrial-truck loading. It is necessary that the platform be designed to support at least half the weight of the loaded truck on the edge of the platform, and it is necessary that the capacity of the elevator be equal to the weight of the automobile truck plus its load.

General Freight Loading. There are many uses for freight elevators having a capacity of 8,000 lb or less in which the building is not adapted to the use of power trucks, and such elevators may be designed on the basis of hand loading. In this case material is moved on and off the elevator either by hand or by means of hand trucks. The weight of these will not, in general, exceed the weight of one-quarter the capacity of the elevator. Many such elevators are used in small warehouses, department stores, and even for some applications in industrial plants where power trucks or automobile trucks are not used. In such cases general freight loading may be specified.

Passenger Loading. The passenger load in multiple-story manufacturing operations must be given serious consideration. The population density on the various floors for some kinds of manufacturing may be higher than for office buildings. In such cases, it is desirable to have a bank of passenger elevators to take care of this traffic. There is considerable interfloor traffic, consisting of supervision, time-study people, manufacturing engineers, etc. A centrally located group of passenger elevators can usually take care of this interfloor traffic most effectively. It is seldom desirable to have the freight elevators centrally located because their location depends on the manufacturing operation being performed. The freight elevators, as part of a manufacturing operation, cannot be interrupted for interfloor passenger traffic. However, it is frequently desirable to utilize freight elevators for passenger service during the morning and evening rush periods. It is often considered impractical to provide a sufficient number of passenger elevators to take care of the incoming personnel in the morning and take them out again at night.

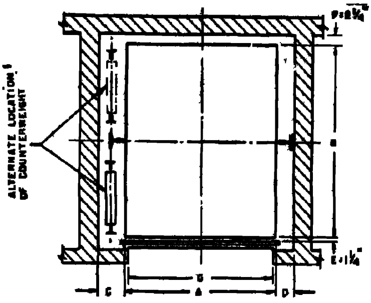
However, if the freight elevators are to be used as passenger elevators during the rush period, they should, from a safety standpoint, be considered as passenger elevators, and the rules of the American Standard Safety Code for Elevators as regards platform loading should be followed. This sometimes gives the elevator a larger capacity rating than it would have if considered purely as a freight elevator. In such cases, the elevator capacity should be selected on the basis of its passenger rating. Because of the tripping hazard, horizontal sliding doors are considered safer for passenger service than are center-parting counterbalanced doors. Counterbalanced doors are best suited for freight elevators because of their trucking sills. A method that has been used to obtain the required safety and still utilize the counterbalanced door is to interlock the hoistway doors with the car gate so that the car gate will not open until the hoistway doors are fully opened. This can be easily installed where power-operated doors are used.

It is difficult to establish any rules for selecting a freight elevator that apply in all cases, as the elevator must be considered as a part of over-all material-handling operation. A few general considerations, however, may be pointed out in connection with all heavy industrial or warehouse elevators.

1. The capacity in pounds and the size and shape of the car should be selected after a careful study of the material to be handled, taking into account its bulk, weight, and the way in which it is packaged.
2. Consideration should be given not only to the material handled by the elevator but also to the forces imposed on the car in loading and unloading if power trucks are used. If the truck is to be hoisted with the material, the rated capacity of the elevator should be made equal to the weight of the truck plus its load.
3. The walls of the car should be kept as smooth as possible by recessing the operating mechanism, such as car-switch or push-button station, and avoiding projections that may become damaged.
4. The sides of the car should be protected by rubbing strips.
5. Suitable trucking sills should be provided on hoistway doors capable of taking the severe loading imposed by power trucks.
6. Careful consideration should be given to the building structure, particularly at the points at which guide rails are supported.
7. The control and operating system should be selected on the basis of obtaining the most efficient service and the greatest flexibility. Collective operation with provision to by-pass, with an attendant service feature and an annunciator, is the most flexible system as it can be used either with or without an attendant.
8. Self-leveling is usually required to correct the stretch of the hoist ropes as heavy loads are run on and off the car. Variable-voltage control gives the best performance for large freight elevators and the most accurate self-leveling.
9. Power-operated hoistway doors and car gates should be used where the service is severe, particularly with large doors.

It is possible, where the service has been carefully studied and the conditions known, to predetermine quite accurately the amount of material that can be handled by an elevator. Certain basic data must be assembled for making this analysis. It is necessary to know the following:

1. The number of floors which the elevator is to serve.
2. The height of each floor.
3. From the above the travel of the elevator for each trip can be determined.
4. An estimate must be made of the number of stops which the elevator will make on each trip, based upon how material is to be handled or picked up.



LOAD	DIMENSIONS				
	A	B	C	D	G
2500	5'-4" 6'-4"	7'-0" 8'-0"	14¼"	8"	5'-0" 6'-0"
3000	5'-4" 6'-4"	7'-0" 8'-0"	14¼"	8"	5'-0" 6'-0"
4000	6'-4" 8'-4"	8'-0" 10'-0"	16¼"	8"	6'-0" 8'-0"
5000	8'-4" 8'-4"	10'-0" 12'-0"	16¼"	8"	8'-0"
6000	8'-4" 8'-4"	10'-0" 12'-0"	16¼"	8"	8'-0"
8000	8'-4" 8'-4"	10'-0" 12'-0"	17½"	10"	8'-0"
10000	8'-4" 10'-4"	12'-0" 14'-0"	18"	10"	8'-0" 10'-0"

FIG. 20-35. Standard elevator sizes. With front and rear openings dimensions *E*, *G*, and *H* apply at both ends

Note A: Platform loading per square foot must comply with local code requirements.

5. Select car size and capacity to handle the particular material involved. Figures 20-35, 20-36, and 20-37 show the dimensions of freight elevators that have been generally used in industry.
6. Select the car speed, based upon the height of the building.

The following is an indication of what should be used.

Table 20-24

Floors	*Speed, fpm*
3	75–100
4–5	150
6–10	200

If one of the floors exceeds 20 ft in height, the next higher speed is desirable.

The time required to make each trip of the elevator is made up of the following:

1. *Running Time.* Running time is equal to the distance traveled divided by the car speed.
2. *Accelerating Time.* Accelerating time consists of the additional time required to accelerate and retard the car for each stop, multiplied by the number of stops made.

3. *Door Time.* Door time is equal to the time required to open and close the car-gate and hoistway doors, multiplied by the number of stops.

4. *Loading Time.* Loading time is the time required to load and unload the car and varies greatly with the type of material to be handled and the method of horizontal material handling used.

Suppose that it is desirable to know how many pounds of material per hour can be handled with an elevator having a capacity of 10,000 lb and a car speed of 150 fpm. This particular elevator has variable-voltage control with automatic self-leveling and has power-operated counter-balanced doors 8 ft high. It is to handle palletized material, and the platform size is such that it can be loaded with four pallets, each weighing 2,500 lb, or three pallets weighing 3,000 lb.

It will be necessary to know from the analysis of the cycle about what the average load will be and how the material is to be distributed over the floors. Let us assume that the elevator is serving a five-floor warehouse. Let us also take the case where the material is brought up to the elevator with power trucks and that in the particular cycle considered most of the material will be taken from the third and second floors and delivered to a loading platform on the first floor and the distance between floors is 17 ft.

The elevator, then, will travel a distance of 34 ft in each trip from the first to the third floor and will make a stop at the second floor in the down direction only. Let us assume that the average load will be three pallets, averaging 2,800 lb in weight. Then the following calculations can be made:

Running time	= (2 × 34 × 60)/150	= 27 sec
Accelerating time	= 3 × 2½	= 7½ sec
Door time	= 3 × 9	= 27 sec
Loading time at 15 sec per pallet	= 3 × 15	= 45 sec
Total		106½ sec

Add 20 per cent, giving a round-trip time of approximately 128 sec.

Trips per hour	= 3,600/128 sec	= 28
Capacity load	= 3 × 2,800 lb	= 8,400 lb
Capacity per hour	= 28 × 8,400 lb	= 235,200 lb

In the above calculations the item that requires the greatest study of actual conditions is the loading time. It is obvious that this will vary over wide limits, depending upon the number of power trucks used, the distance from which the material must be brought up and the method of loading employed. Where there is a continuous flow of material, very satisfactory results can be obtained with two

elevators, so that one elevator is being loaded while the other is being unloaded. In this case the material that the elevator will handle can easily be made equal to the amount of material that can be brought up with the power trucks.

ELEVATOR MAINTENANCE

Elevators may be well designed and carefully selected for a particular service, but the best performance and long life can be obtained only if they are properly maintained. The objects of elevator maintenance are

1. To provide a maximum of uninterrupted service
2. To ensure long life of the equipment
3. To ensure safe operation

An elevator is an assembly of many difficult kinds of mechanism, some of which are quite intricate. Therefore, good adjustment, cleanliness, and adequate lubrication are prime essentials. Certain parts are subject to natural wear and tear and should be replaced from time to time before the failure causes an interruption to service or creates a hazard.

Good maintenance may be referred to as protective maintenance, as distinguished from mere trouble shooting, which corrects a fault only as trouble develops to a point where it causes faulty operation or a shutdown. Under protective maintenance, wearing parts, such as contacts, guide shoes, contact or shunts, and other similar parts are regularly inspected and replaced when it appears that they are approaching the end of their reliable life.

There are certain requirements that must be followed if good maintenance is to be obtained. One of the most important of these requirements is to have a maintenance staff with a thorough knowledge of the equipment. Unskilled persons may often do more harm than good by improperly diagnosing a fault and applying a wrong corrective. The symptoms of trouble should be recognized quickly and the basic source of the trouble immediately corrected. Lack of knowledge and skill leads to long shutdowns while trouble is being located and to improper steps taken in the correction of it.

To ensure a minimum of shutdowns, a regular schedule of maintenance is desirable. This schedule lists all the work that is to be done such as oiling, cleaning, inspecting, adjusting, etc. These steps should be regularly and periodically taken. Regular inspections at scheduled times should be made.

It is useful to make a log of all the troubles that occur. It is seldom that maintenance is perfect, and some trouble and occasional shutdowns may occur. If these troubles are recorded, together with their true cause, and a statement of what was done to correct it, a record will eventually be had which will be very useful as a guide for inspection and replacement.

It has been pointed out that the replacement of wearing parts should be made before they become so badly worn as to cause a shutdown or an unsafe condition. Every elevator should be equipped with a mileage recorder and a stop recorder in order that there be available a record of just how much service is being obtained. This service record, together with the trouble log, may be used as a basis for a systematic replacement of wearing parts before they become troublesome. In the replacement of parts experience with a particular installation, if systematically recorded, will furnish the best guide.

It is needless to say that, to accomplish all this, an adequate organization is necessary. Where there are a large number of elevators, a staff of maintenance men under good supervision may be employed continuously for elevator maintenance. Where there are only a few elevators, it usually becomes necessary either to maintain them by personnel who also maintain a great deal of other equipment about the plant or to have the maintenance done by others. Practically all elevator manufacturers keep a regular organization for maintaining elevators of their own manufacture. These manufacturers will enter into maintenance contracts of various types depending upon the nature of the installation. In considering the maintenance of an elevator or a group of elevators, such maintenance contracts should receive serious consideration.

INDUSTRIAL PROCESS AIR CONDITIONING

BY ALFRED B. WASON

Assistant Manager, Heating and Air Conditioning Department, and Manager, Industrial Air Conditioning Section, of the Westinghouse Electric Corporation, Sturtevant Division

INTRODUCTION

Industrial process air conditioning conveys so many different concepts in the mind of the industrial engineer that the expression requires clarification. The industrial engineer is primarily concerned with the atmospheric conditions affecting the manufacture, preparation, process, storage, and preservation of material, equipment, and commodities. The fundamental basic factors which control these conditions are temperature, relative humidity, air circulation, and air purity, of which one or more may be the governing factor or factors. The optimum atmospheric conditions to be maintained depend upon the physical and chemical characteristic properties of the product, generally hygroscopic, and the nature of the process of manufacture.

Industrial process air conditioning may be defined as the art of simultaneously controlling the temperature, relative humidity, ventilation, cleaning, and movement of the air within an enclosure intended for the manufacture of a product sensitive to atmospheric conditions.

PSYCHROMETRY

Psychrometry is a branch of physics relating to the measurement or determination of the physical properties of atmosphere air, with particular reference to its moisture-vapor properties.

Fundamental Definitions, Laws, and Principles

To understand industrial process air conditioning, it is essential to have a general knowledge of the atmosphere surrounding the earth, which we call air, its most important physical properties, and the relations between these properties under variable conditions, and further, a practical knowledge of the instruments commonly used for measuring these properties. The composition of air is a physical mixture of vapors, gases, and dust which may be considered divided into four separate classifications, as follows:

1. The major constituents of air by volume are nitrogen, 78.1 per cent; oxygen, 21 per cent; and a small volume, 0.9 per cent, of inactive gases, principally argon. These constituents are present in the air in almost constant proportions.
2. Air includes accidental or foreign gases, such as toxic gases, odors, sulfur dioxide, ammonia, and carbon dioxide, which affect the air required for ventilation to more or less a degree in process air conditioning.
3. Air contains water vapor, moisture in gaseous state, which is the most important factor in considering atmospheric-sensitive products for manufacture.
4. Air contains solid-matter dirt, carbon particles, smoke bacteria, or any foreign particles generally termed dust which are suspended in the air.

The effects which the various components of the air have on industry are tremendous, particularly in the economics of manufacture and in personnel and healthful conditions. Especially is this true of water vapor present in the air. Fortunately, the above factors are to a large extent controllable by means of suitable equipment, properly operated and regulated to maintain the desired air conditions as required for manufacture.

Physical Properties of Air

Atmospheric air has six physical properties most applicable to process air conditioning. These are density or weight, pressure, temperature, heat content, humidity or moisture vapor, and velocity.

Density. Density is defined as the weight of a unit volume of a substance. The density of air is measured in pounds per cubic foot under specified conditions of temperature and pressure. Thus the density of air at 68°F and atmospheric pressure is 0.075 lb per cu ft.

Specific volume is the reciprocal of density. It is defined as the volume occupied by the unit weight of a substance under specified conditions of temperature and pressure and is measured in cubic feet per pound. Thus the specific volume of air at 68°F and atmospheric pressure is 13.3 cu ft per lb.

The atmospheric air totally envelops the earth, moving with it, and would remain stationary with reference to terrestrial objects except for local changes in temperature and moisture content, effecting change in density and producing winds, rain, snow, and storms. Pressure differences reflect these changes.

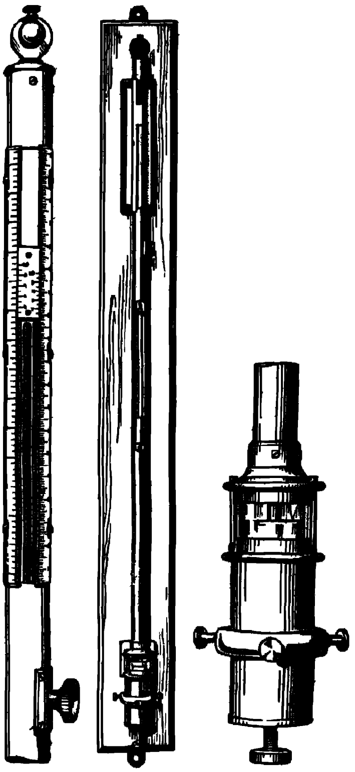

Fig. 21-1. Mercury barometer with enlarged reading scale and mercury well. Adopted by the United States Weather Bureau.

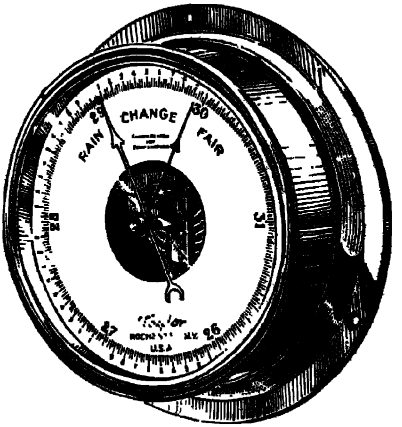

Fig. 21-2. Aneroid barometer.

Pressure. Air has appreciable density and constantly exerts an atmospheric pressure, termed "barometric pressure," which exerts a force which is equal to the weight of a column of air 1 sq in. in section through the whole layer, variously estimated at from 40 to 200 miles in depth, above which is interplanetary space. The normal or standard "barometric pressure" at sea level is 29.92 in. Hg, (slightly less at the equator), which corresponds to a pressure of 14.7 psi or, expressed another way, to the pressure of a column of water 34 ft high. As the altitude above the sea level increases, the atmospheric pressure decreases, which amounts to about ½ psi for each 1,000 ft rise for the first mile in height.

Barometer. The "barometer" is an instrument for measuring the pressure of the atmosphere. The standard instrument for this purpose is the mercury barometer which is designed to balance automatically the pressure of the atmosphere against the weight of a vertical column of mercury. A tube containing a column of mercury is inverted, and the open end is sunk in a cup containing mercury, which is exposed to the pressure of the atmosphere. The upper end of the tube is closed, and a vacuum exists between it and the column of mercury. The difference in height between the level of mercury in the cup and in the tube is the "height of the barometer"—a direct measure of atmospheric pressure (see Figs. 21-1 and 21-2).

Inches of mercury are readily convertible to pounds per square inch since 1 in. Hg is equivalent to 0.4912 psi, or conversely, 1 psi is equivalent to 2.036 in. Hg.

Gauge Pressure. Gauge pressure is the pressure measured above atmospheric pressure as a base, expressed in pounds per square inch (see Fig. 21-3).

Absolute Pressure. Absolute pressure is the sum of the gauge pressure and barometric pressure, or the total pressure above a perfect vacuum, expressed in pounds per square inch.

Vacuum. Vacuum is the pressure measured below atmosphere as a base, expressed in inches of mercury (see Fig. 21-4).

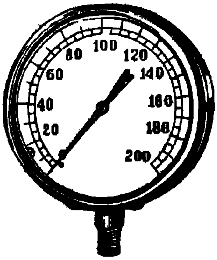

FIG. 21-3. Pressure gauge.

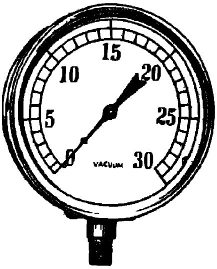

FIG. 21-4. Vacuum gauge.

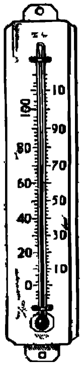

FIG. 21-5. Industrial thermometer

Temperature. Physics defines temperature as a measure of molecular activity, which is closely associated with the heat content of a substance and is measured by a conventional thermometer (see Fig. 21-5). It is generally termed the dry-bulb temperature. The temperature scales most generally used are Fahrenheit (F) and centigrade (C), the former being the most common.

$$C = \tfrac{5}{9}(F - 32) \qquad F = \tfrac{9}{5}C + 32$$

Absolute Temperature. Absolute temperature is obtained by adding 459° to the Fahrenheit temperature or 273° to the centigrade temperature.

The relationship of the three preceding physical properties of air—density, pressure, and temperature—and their performance may be further explained by the fundamental laws of perfect gases.

Law of Gases

Density of air varies with changes of temperature and pressure and performs practically in accordance with the fundamental laws of perfect gases which are

1. At a constant temperature the volume varies inversely as the absolute pressure (Boyle's law).

2. At a constant pressure the volume varies directly as the absolute temperature (Charles's law).

3. At a constant volume the pressure varies directly as the absolute temperature (Charles's law).

Combining the above laws, the general relationship becomes

$$PV = KT$$

where P = absolute pressure, psi
V = volume, cu ft/lb
K = a constant (for air 0.370)
T = absolute temperature, deg F

Density of air at atmospheric pressure, 29.92 in. Hg, at 68°F, and 50 per cent relative humidity is approximately 0.075 lb per cu ft. This figure is generally accepted for fan-rating-table performances.

Physical State of Matter. All matter exists in one or another of three different states as a solid, liquid, or gas.

Water (H_2O) can exist as a solid (ice), as a liquid (water), and as a gas (aqueous vapor or steam). The physical change in state of water with variations in temperature and pressure in combinations with air are the factors involved in psychrometry.

To illustrate, compare the relative amount of space occupied by a given weight of water in the three physical states, as shown in Table 21-1.

Table 21-1

Physical state, atmospheric pressure	Density, weight per cu ft, lb	Relative volume occupied by equivalent weight of water, cu ft
Solid (ice at 32°F)	57.5	1.09
Liquid (water at 60°F)	62.37	1.00
Gas (steam at 212°F)	0.037	1,690.0
Aqueous water vapor at 68°F and 50 per cent relative humidity	0.00054	115,500.0

Note the amazing difference in volumes between 1 cu ft of water (liquid) and the same weight of water vaporized (gas) at atmospheric conditions.

Heat. Heat is a form of physical energy existing within a substance because of molecular activity. Heat is one form of energy. There are many others, and all are mutually convertible under the laws of conservation of energy. The quantity of heat per pound of a material is generally expressed in Btu (British thermal unit). Water is taken as the standard unit of heat, and 1 Btu is defined as the heat required to raise 1 lb of water 1°F. The French thermal unit is the calorie, which is the heat required to raise 1 kg of water 1°C.

$$1 \text{ Btu} = 0.2520 \text{ calorie} \qquad 1 \text{ calorie} = 3.968 \text{ Btu}$$

Mechanical energy is measured by the foot-pound, which is the amount of work required to raise 1 lb weight 1 ft vertically against gravity. Expressed in heat equivalent, 1 Btu = 778 ft-lb. Power is the rate of doing work expressed in horsepower. One horsepower is the power to do work at the rate of 33,000 ft-lb per min. Expressed in heat equivalent, 1 hp = 42.42 Btu per min, or 2545 Btu per hr. Work and power are frequently expressed in electrical terms, the unit of work being the watthour or kilowatthour and the unit of power being the watt or kilowatt (1,000 watts).

$$1 \text{ hp} = 746 \text{ watts} \qquad 1 \text{ kw} = 1.341 \text{ hp}$$

Specific heat is defined as the number of Btu required to raise the temperature of 1 lb of a substance 1°F or the number of calories required to raise 1 kg 1°C. Water is taken as the unity of standard for specific heat, expressed 1.0. The specific heat of air at constant pressure and at ordinary temperature is 0.2375, usually figured as 0.24.

Sensible heat is the heat represented by a change in dry-bulb temperature either added to or subtracted from a substance.

Latent Heat of Fusion. To change the physical state of a substance such as ice, an appreciable amount of heat must be added. Suppose 1 lb of ice is heated under atmosphere conditions (29.92-in. barometer) from 0 to 32°F; 15.4 Btu will be required since the specific heat of ice is 0.48. Further addition of heat will cause the ice to melt, the temperature remaining constant. To melt the whole pound of ice will require 144 Btu at 32°F. This 144 Btu is called the "latent heat of fusion of ice."

Heat of the Liquid. When the pound of ice is all melted, further addition of heat will cause the temperature of the water to rise until the boiling point is reached at 212°F. The amount of heat required to raise the temperature of water from 32°F to any given temperature is called the "heat of the liquid." The heat of the liquid is determined by multiplying the temperature degree rise times the specific heat of the liquid. The heat of the liquid for water from 32 to 212°F is 180 Btu.

Latent Heat of Vaporization. Further addition of heat to the pound of water at 212°F will cause boiling, the temperature remaining constant, until all the water is evaporated. To vaporize the whole pound of water will require 970 Btu. This is defined as the "latent heat of vaporization." Water will vaporize at temperatures below the boiling point under various conditions, and the lower the temperature, the higher the latent heat of vaporization. Thus to evaporate 1 lb of water from a humidifier at 60°F requires 1058 Btu. Whenever evaporation takes place, heat must be supplied either from some source added to the air or by heating the water.

Total Heat of Steam. The total heat of steam is the amount of heat required to convert 1 lb of water at 32°F to 1 lb of steam at any given temperature and pressure. For example, total heat of dry saturated steam at 212°F is 180 + 970 = 1150 Btu per lb.

Saturated and Superheated Steam. If the process is continued and additional heat is added to the 1 lb of steam, completely evaporated, the temperature will rise, and the steam will now become "superheated," or "dry saturated." Should any particles of free moisture be carried into the space containing the steam vapor and the space thus contain all the steam vapor it can hold, the condition is called "wet saturated."

The preceding explanation of the physical change of state of water from ice (solid), water (liquid), steam, or vapor (gas) is generally understood; however, this same process takes place at atmospheric pressures at ordinary temperatures and thus explains the fundamental process of psychrometry. The air-washer type of spray humidifier is frequently referred to as a "boiler at atmospheric pressure." The process of evaporation under normal atmospheric temperatures and pressures is similar to the evaporation process of the ordinary boiler at higher temperatures and pressures within a closed space.

Total Heat. In atmospheric air, water vapor exists in varying amounts simultaneously with temperature variations. Total heat is the sum of the latent heat of the water vapor plus the sensible heat of the air mixture (air and water vapor). The wet-bulb temperature is the measure of the total heat. At a constant wet-bulb temperature the total heat remains constant irrespective of any change in temperature or relative humidity (see Table 21-3, page 1469).

Wet-bulb Temperature. Wet-bulb temperature or thermodynamic wet-bulb temperature is the temperature at which a liquid (water), by evaporating into the surrounding air, can bring the air to saturation. The wet-bulb thermometer is an ordinary dry-bulb thermometer with a clean piece of cloth or wick covering the bulb. This bulb, wet with water and with vigorous movement of air across the wick, will cause evaporation from the wetted surface of the wick, lowering the temperature below the dry-bulb temperature in direct proportion to the amount of moisture in the air. The difference in reading between the dry-bulb and wet-bulb temperatures is termed the "wet-bulb depression." This is a direct means of determining the wet-bulb temperature, a measure of the total heat of the air. The wet-bulb depression is the temperature at which the air would saturate without a change in total-heat content.

Sling Psychrometer. The sling psychrometer, the standard instrument adopted by the United States Weather Bureau, is the most reliable device for determining the dry-bulb and wet-bulb temperatures, from which readings determination of the dew-point temperature and relative humidity can readily be obtained by reference to psychrometric tables or charts. This instrument consists of a pair of standard thermometers, with one bulb covered with a silk or muslin cloth, mounted and attached to a handle. After wetting the wet-bulb wick, the instrument is swung rapidly causing the thermometers to respond quickly and accurately to the dry-bulb and wet-bulb temperatures. *Caution:* the wick must be clean. This is the most practical and accurate method in determining the psychrometric conditions of the air and is used to adjust or calibrate other atmospheric reading instruments and devices (see Figs. 21-6, 21-7, 21-8 and 21-9).

Saturated Air, Dew Point, Vapor Pressure, and Evaporation. *Saturated Air.* Water vapor has one most important physical characteristic different from all the other components of atmospheric air, *i.e.*, the *temperature* is the sole determining factor of the weight of water vapor which can exist in a given volume of space. When the given volume of space contains the limiting maximum of water vapor (expressed in grains per cubic foot), this condition is termed "saturated air." Temperature is the only factor affecting this maximum condition, and the amount of water vapor each cubic foot can hold will increase and decrease with the temperature. Thus the presence of the air in a space has no effect on the maximum amount of vapor in that space. For example, in a perfect vacuum the maximum amount of vapor per cubic foot within the given space will be determined solely by the temperature. The same condition would exist with air present at the same temperature (see Table 21-2, page 1468).

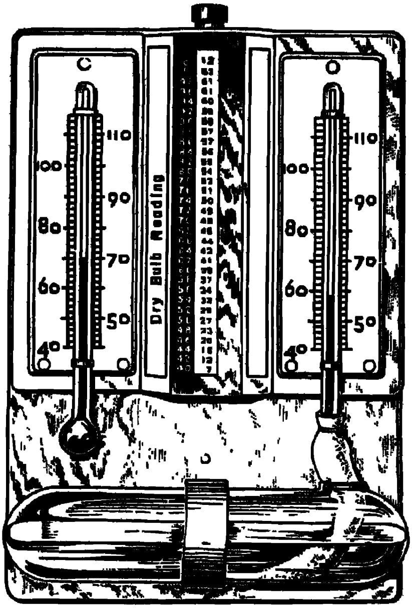

FIG. 21-6. Humidiguide—wet-bulb and dry-bulb temperatures with revolving humidity tables at the vertical center for computing the relative humidity.

Dew Point. The temperature corresponding to saturation for a given moisture content is termed the "dew-point temperature." When water vapor is present in the air to a lower extent than saturation, it is termed "superheated" since the temperature may be lowered without condensation. Should the temperature of the air be lowered to the point corresponding to the saturation point for the weight of vapor present per cubic foot, the temperature at which saturation occurs is termed the "dew point."

Vapor Pressure. The pressure exerted by the water-vapor component of the existing atmospheric pressure is termed vapor pressure and is measured in inches of mercury. Water vapor tends to saturate the surrounding space and exerts a pressure

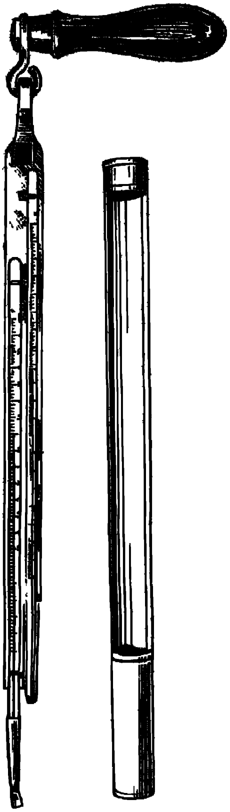

Fig. 21-7. Sling psychrometer standard type with carrying case. Adopted by the United States Weather Bureau.

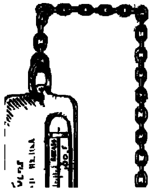

Fig. 21-8. Sling psychrometer pocket type. This sling is one-half the size of sling shown by Fig. 21-7.

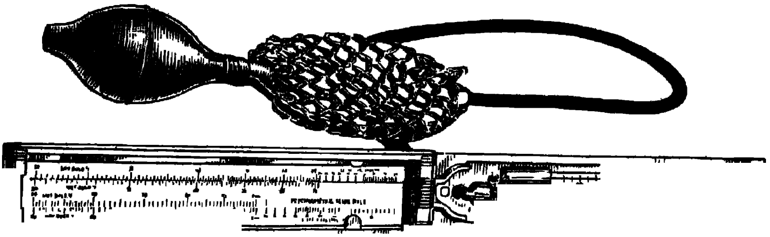

Fig. 21-9. Sling psychrometer—hand-aspirated type with psychrometric slide rule for computing the relative humidity.

which varies with the density of the vapor. At a given temperature, the vapor pressure may vary with the amount of vapor present but cannot exceed the maximum which exists when the space is saturated. Vapor pressure increases as the temperature increases.

Evaporation. The physical characteristic of evaporation of water or vaporization is due to opposing molecular forces tending to come to equilibrium. The rate of evaporation may be slow, as at ordinary temperatures, or may be rapid when water is actually boiling. The temperature is the controlling factor as to the maximum possible weight of vapor per cubic foot. However, the atmospheric pressure will affect the rate at which evaporation of water takes place. For example, in a perfect vacuum, water would instantly "flash" into vapor and diffuse within the contained space. As water vapor increases in partially saturated air, the vapor pressure increases until equilibrium between the vapor pressure and the evaporative force is established at saturation. To obtain complete saturation, the atmosphere must be confined in a closed space; otherwise vapor will diffuse rapidly to less humid surrounding areas. This is also true for areas where partial saturation is maintained within a confined space.

The factors affecting the rate of evaporation of water from a free surface, are a rise in temperature, an increase in surface area, and an increase in air velocity over the surface area. There are other factors that will increase the rate of evaporation under control of normal atmospheric conditions, such as a decrease in atmospheric pressure or a reduction in the amount of vapor present in the surrounding air.

The terms "atmospheric pressure," "barometric pressure," "vapor pressure," "water vapor," and "steam" should be clearly understood. The expressions "water vapor" and "steam" are synonymous, but customarily water vapor or aqueous vapor refers to atmospheric moisture, whereas steam refers to water vapor within a closed space, unmixed with air, more particularly at temperatures at or above the boiling point.

Humidity. Humidity refers to moisture or water vapor mixed with atmospheric air in the form of vapor.

Absolute Humidity. Absolute humidity refers to the weight of water vapor per unit volume (vapor density) expressed in grains of water vapor per cubic foot. This term, "absolute humidity," is precise as to the weight of water vapor per unit volume regardless of its temperature or whether or not the air is saturated.

Relative Humidity. Humidity as above defined refers to moisture or water vapor mixed with atmospheric air. It therefore follows that relative humidity implies the degree or amount of moisture vapor present within a given space. Then relative humidity may be defined as the ratio of the actual weight of water vapor per cubic foot (vapor density) to the maximum weight of water vapor per cubic foot at saturation at the same temperature expressed as a percentage. Thus saturated air has a relative humidity of 100 per cent. Since the laws of perfect gases apply to vapors (gases), the volume of 1 lb of aqueous vapor at a constant temperature varies inversely with the vapor pressure. The vapor pressure, therefore, is always proportional to the weight of water vapor per cubic foot (absolute humidity) at a given temperature. For every temperature at which saturation occurs (dew point), there is a corresponding value of vapor pressure. Therefore, the relative humidity may be expressed in terms of the ratio of the actual vapor pressure in the air to the vapor pressure at saturation at the same temperature, expressed as a percentage. Thus relative humidity may be expressed by a ratio of either *vapor density*, *absolute humidity*, or *vapor pressure.*

The amount of moisture present in the air is solely a function of the temperature. It therefore follows that the presence of air has nothing to do with the relative humidity in a given space. Relative humidity is frequently spoken of as "humidity," meaning per cent of saturation or degree of saturation. The tremendous effect temperature has on the capacity of air to hold moisture vapor may be illustrated by the following example: air at 35°F saturated contains 2.38 grains per lb; air at 110°F saturated contains 26.34 grains per lb, or more than eleven times as much.

Humidity Ratio. Humidity ratio is the weight of water vapor per pound of dry air, sometimes called specific humidity, expressed in grains per pound of dry air.

Humidity Percentage. Humidity percentage is the ratio of the actual weight of water vapor mixed with 1 lb of dry air to the weight of saturated water vapor mixed with 1 lb of dry air at the same temperature, expressed in percentage.

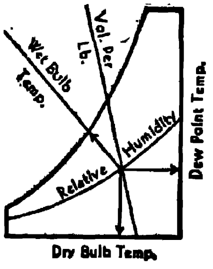
Relation of Dry-bulb, Wet-bulb, and Dew-point Temperature and Relative Humidity

The relation between the dry-bulb and wet-bulb temperature, dew point, and relative humidity are of concern to "psychrometry." Physical properties of atmospheric moisture should be thoroughly understood in order to have a clear conception of humidity. As previously explained, the wet-bulb temperature is lower than the dry-bulb temperature owing to cooling by evaporation, except at saturation, when the dew-point, dry-bulb, and wet-bulb temperatures read exactly the same. As previously stated, wet-bulb temperature is the function of the total heat of the air (air and moisture); thus when the dry-bulb and wet-bulb temperatures are known, the dew point and relative humidity corresponding to those conditions can be readily determined. It further follows that, when any two of the four factors—dry bulb, wet bulb, dew point, and relative humidity—are known, the other two are fixed and are readily determined from reference to psychrometric tables or charts. It is generally more convenient and practical to use the psychrometric chart because the graphical presentation substantially aids visualization, and degree of accuracy is ordinarily within practical application for most calculations. There are many types and arrangements of psychrometric charts in use, such as those prepared by W. H. Carrier, E. V. Hill, General Electric, Sturtevant, and Westinghouse, all of which have merit. For convenience, charts of the Sturtevant and the Westinghouse "Psychrograph" are given for reference applications (see Figs. 21-10 and 21-11).

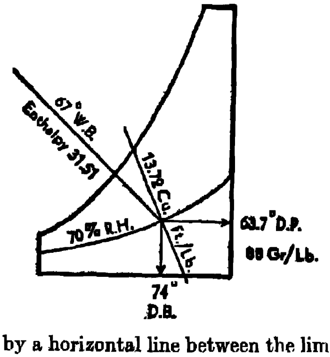
With careful study of these charts, proficiency and accuracy can readily be obtained in converting and interpreting these physical factors of psychrometry to the particular problems of process air conditioning.

Directions for Using the Sturtevant Chart (Fig. 21-10)

If any two properties of air are known, all others may be found.



Numerical values of properties may be read directly.



Sensible heating and cooling is represented by a horizontal line between the limits of the process. All the properties of air change except the moisture content.

EXAMPLE: Air initially at 90° dry bulb is heated to 105° dry bulb.

	Initial	Final
Dry bulb	90°	105°
Wet bulb	71°	75°
Relative humidity	40 %	26.0 %
Grains/lb	84	84

	Initial	Final
Dew point	62.4	62.4
Vapor pressure	0.562	0.562
Enthalpy	34.83	38.46
Cu ft /lb	14.12	14.5

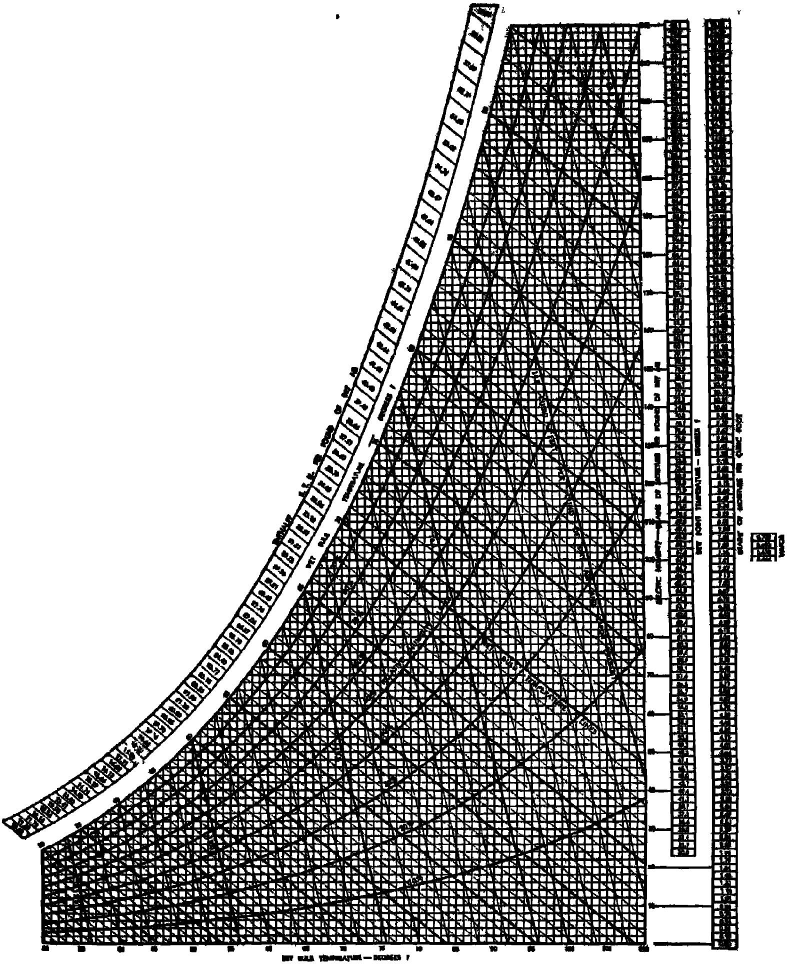


Fig. 21-10. **Sturtevant psychrometric chart.**

Humidifying and Dehumidifying with no change in dry bulb is represented by a vertical line between the limits of the process.

Example: Air at 90° dry bulb and 84 grains per lb is humidified without change of temperature to 128 grains per lb.

	Initial	Final		Initial	Final
Dry bulb	90°	90°	Dew point	62.4	74.3
Wet bulb	71°	78°	Vapor pressure .	0.562	0.854
Relative humidity.	40 %	60 %	Enthalpy .	34.83	41.42
Grains/lb	84	128	Cu ft/lb	14.12	14.26

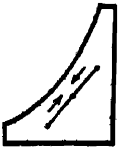
Evaporating cooling is accomplished by passing air through a spray or finely divided curtain of recirculated water, and is represented by a line of constant wet-bulb temperature. Sensible heat is absorbed in evaporation, thereby increasing the moisture content while the total heat remains constant.

EXAMPLE: Air at 90° dry bulb and 40 per cent relative humidity is passed through a spray of recirculated water. The water temperature will approach the wet-bulb temperature of the air which remains constant.

	Initial	Final
Dry bulb	90°	72°
Wet bulb. . . .	71°	71°
Relative humidity.	40 %	95 %
Grains/lb	84	112

	Initial	Final
Dew point	62.4	70.5
Vapor pressure. . .	0.562	0.747
Enthalpy.	34.83	34.83
Cu ft/lb	14.12	13.74

Temperatures of a Mixture. Find the final wet- and dry-bulb temperatures of a mixture of 3,000 cfm at 60° dry bulb and 46° wet bulb and 5,000 cfm at 80° dry bulb and 63° wet bulb. Read from constant-volume lines on chart,



3,000 cfm	60° dry bulb	46° wet bulb	13.17 cu ft/lb
5,000 cfm	80° dry bulb	63° wet bulb	13.85 cu ft/lb

$$\frac{3{,}000}{13.17} = 228 \text{ lb/min} \qquad \frac{5{,}000}{13.85} = 361 \text{ lb/min}$$

$$228 + 361 = 589 \text{ total wt of air per min}$$

Dry-bulb temperature of the mixture

$$(228/589) \times 60 = 23.25^\circ \qquad (361/589) \times 80 = 49.10^\circ$$
$$23.25 + 49.10 = 72.35^\circ \text{ final dry bulb}$$

Wet-bulb temperature of the mixture

$$\text{Enthalpy at } 46^\circ \text{ wet bulb} = 18.12 \text{ at } 63^\circ \text{ wet bulb} = 28.48$$
$$(228/589) \times 18.12 = 7.01 \qquad (361/589) \times 28.48 = 17.45$$
$$7.01 + 17.45 = 24.46 \text{ enthalpy of mixture}$$
$$\text{Corresponding wet-bulb temperature} = 57^\circ \text{ final wet bulb}$$

Application of the Fundamental Law of Saturation. The fundamental law of saturation is expressed as "cooling by evaporation," which is cooling the air by the evaporation of moisture. This has practical application to humidifiers of all spray types when recirculating water at ordinary temperature. When passing air through a spray-type humidifier, in which no heat is added or subtracted from the air, the air will *saturate* at the *entering wet-bulb temperature*, the function of the total heat of the air. The process of saturating the air has been an exchange of heat by lowering the sensible heat by exactly the latent heat gained by the evaporation of moisture. This is an adiabatic condition of saturation at constant wet-bulb temperature. Since there is no change of total heat, the dry bulb, dew point, and relative humidity will vary until saturation occurs. The application of this fundamental law of saturation to spray-type humidifiers simplifies calculations for determining the leaving humidifier conditions (fixed dew point, moisture content of the air) for process air conditioning.

For calculations of spray-type humidifiers requiring the addition of heat or cooling by artificial source (well water or refrigerated chilled water), the above statement does not apply.

Velocity. Velocity expresses movement of air, generally flowing through a large duct, under low heads and provides the mechanical means of conveying the conditioned air, heat, and moisture, in sufficient volume, to or away from the materials in process being treated. The ultimate effectiveness and efficiency of industrial process air-conditioning operations depends upon this all-important factor—air circulation.

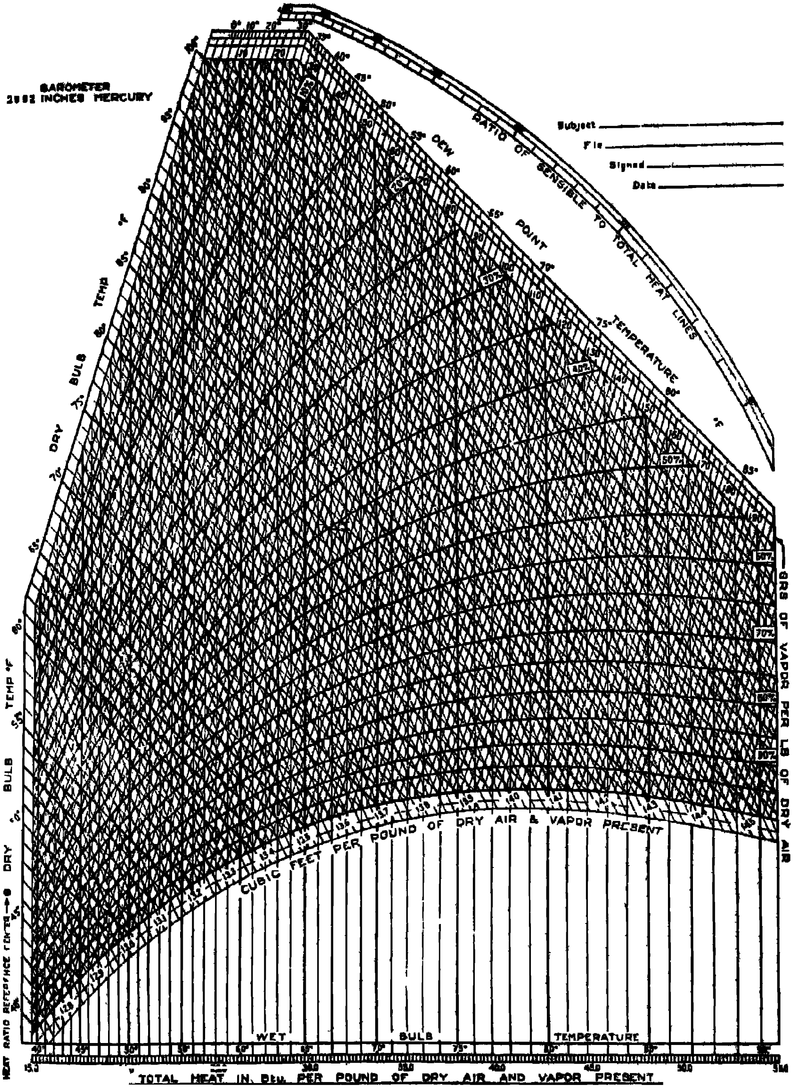


FIG 21-11. Westinghouse psychrograph

Measurements of velocity pressure and static pressures are generally made with a pitot tube to determine the velocity, expressed in feet per minute or feet per second (see Figs. 21-12 and 21-13)

Table 21-2. Properties of Air Saturated with Water Vapor

Temp, deg F	Pressure of water vapor		Weight of water vapor to saturate 1 lb dry air		Volume, cu ft		Enthalpy, Btu per lb dry air		
	In. Hg	Psi	Lb	Grains	1 lb dry air	1 lb dry with vapor to saturate	Dry air (sensible heat)	Vapor to saturate (latent heat)	Saturated mixture (total heat)

PROPERTY CHARACTERISTICS OF PROCESS MATERIALS

Industrial process air conditioning covers a broad field and is frequently confused with the *process drying of materials*. The distinction must be clearly defined so that the manufacturer handling atmospheric-sensitive products will understand the fundamental principles involved between process air conditioning and process drying of materials, thus enabling him to classify the process procedure adequately. Briefly, the distinction between these process classifications may be stated as follows: process air conditioning means controlled humidity of the air *controlling the moisture content* within the product, whereas process drying means *removal of water content* by evaporation within the product. The discussion in this text will be limited to process air conditioning.

Physical Combination of Water with Solids. Water associates with solids in various combinations, *e.g.*, free moisture on the surface of a substance, water held within the pores or interstices of a solid, particles suspended in the water, and crystalline formation, or a substance which absorbs or retains moisture. The last is known as the hygroscopic characteristic of a substance. Water combinations with materials may be in one or more of these physical states. The last, hygroscopic material, is the most common combination met in process air conditioning. Hygroscopic materials are those which readily absorb and retain moisture and at a fixed temperature have the quality to absorb a fixed percentage of their own weight of moisture from the surrounding atmosphere containing a fixed amount of water vapor.

Process Classification. Products for manufacture may be classified as chemical, crystalline, metallic, fibrous, or hygroscopic materials. Process air conditioning may be broken down into control of rate of chemical reactions, control of rate of crystallization, control of corrosion of metals, moisture control of fibrous or hygroscopic material, and elimination of static electricity.

Control of Chemical Reactions. The control of chemical reactions is primarily the function of controlling the temperature, thus regulating the rate of the chemical reactions, although some chemical products require control of both the temperature and humidity. For example, rayon manufacture would be a typical illustration in the mercerizing process where temperature controls the rate of reaction and relative humidity controls the rate of evaporation. The dough room in the baking industry is a typical example of biochemical reaction. The temperature controls the rate of fermentation of yeast, and the relative humidity prevents crusting of the surface of the dough, allowing carbon dioxide gases formed by fermentation to pass freely through the surface of the dough.

Control of Crystallization. Crystallization is the process of forming crystals by controlling the rate of cooling of a saturated solution. The temperature controls the size, whereas the relative humidity controls the rate of evaporation, regulating the density of the solution. The coating of pills is a typical example. A heavy solution of sugar is added to the tumbler, and as the water evaporates, crystals of sugar form on the surface of the pills. Close control of temperature produces a fine, clear, smooth coating on the pills, and the relative humidity regulates the rate of evaporation. This process is frequently referred to as control of the dry-bulb and wet-bulb temperatures, since the product temperature approaches the surrounding wet-bulb temperature owing to evaporation.

Control of Corrosion of Metals. Manufacture of precision instruments requires close tolerance limitations, protection against corrosion, uniformity, elimination of dust and injurious gases, and improved employee efficiency. The manufacture of gauges is a typical example where accurate control of temperature assures uniformity of tolerance standards, tooling, assembly precision, calibration, reduction of scrap; clean air avoids spoilage or rejects from dirt particles; removal of gases harmful to health and low relative humidity reduce corrosion caused by perspiration from worker's hands; comfortable conditions increase employee accuracy of workmanship and personnel efficiency.

Control of Moisture Content of a Fibrous or Hygroscopic Material. Moisture content of a hygroscopic material is a general term and refers to either free-moisture content (wet cloth) or hygroscopic moisture (regain) which varies with atmospheric conditions. To clarify this distinction between moisture content and moisture regain, suppose, for example, a piece of cloth is soaking wet. The moisture content may be 75 per cent of the total weight. If the cloth is hung up to dry, the free moisture will run off or evaporate, and the cloth eventually will be dry with no apparent surface moisture. However, there is still hygroscopic moisture present in the cloth. The amount will be proportional to the prevailing conditions of the surrounding atmosphere. If this cloth is placed in a heated dry atmosphere, it will continue to lose weight until an equilibrium point is reached. No further loss in weight will occur. This final constant weight is the "dry weight" frequently referred to as "the bone-dry weight." Then the moisture content is the sum of free moisture and hygroscopic

Table 21-4. Regain of Hygroscopic Materials*

(Moisture content expressed in per cent of dry weight of the substance at various relative humidities—temperature, 75°F)

moisture contained in a material, expressed as a percentage of the *gross* weight of the material The regain is the hygroscopic moisture only contained in a material, expressed as a percentage of the bone-dry weight of the material The regain of a hygroscopic material will depend upon the physical characteristics of that material, the temperature, and especially upon the relative humidity of the surrounding atmosphere The temperature and relative humidity control the hygroscopic moisture content of materials and correspondingly affect the physical properties of a material—weight, strength, pliability, flexibility, softness, stretch, quality, appearance, and facility of process of manufacture Different materials contain various percentages of moisture after continued exposure to atmosphere Likewise, the rate of absorption or loss of moisture varies with the thickness and density of the material. The fact that hygroscopic materials come into equilibrium with the surrounding air is the fundamental basis for the control of the physical properties during the process of manufacture (see Table 21-4).

Classification of Industry. Industrial process air conditioning concerns the atmospheric conditions required for the process and preservation of materials for manufacture. Requirements within the range of human comfort may be maintained within the manufacturing areas, but when atmospheric conditions are not within the range of human comfort, special consideration must be made, within a closed space, for maintenance of required conditions. The most favorable temperature and relative-humidity requirements may range as low as 5 per cent relative humidity in certain applications to a condition approximating saturation in other applications. Variations of maintained atmospheric conditions will often occur within the same industry, depending upon the process of manufacture, and frequently a compromise is required where the employee's health and comfort are concerned. The ideal atmospheric conditions have been established for many industrial applications, but when the requirements are unknown, special laboratory tests will be required to determine the optimum atmospheric conditions (see Table 21-5).

LOAD SURVEY AND CALCULATION OF REQUIREMENTS

The standard of industrial process air conditioning, as previously defined, is simultaneous control of temperature, relative humidity, ventilation, air purity, and air movement. The design of an air-conditioning system for any treated space must conform to these standards. Before designing a system for process air conditioning, it is necessary to organize and assemble all available information and data. This information will include geographical location, building plans, outside atmospheric conditions, inside temperatures and relative humidity desired for summer and winter, layout of machinery, internal heat loads, number of occupants, lighting, machinery horsepower, and all other heat-producing factors, as well as a study of the removal of obnoxious fumes or gases for proper ventilation, elimination of dust, moisture gain or loss within the treated area, air distribution, an analysis of the economic situation, and any other factors affecting the design. For convenience refer to Figs. 21-14, 21-15, and 21-16, which give a summary of information desired before preparing calculations. This format was primarily designed for an existing building but is equally applicable to assembling data for a new building project. Since the entire subsequent estimate is based on the data shown on the survey sheet, it follows that a careful study and analysis must be made before an accurate engineering determination can be calculated to meet load requirements.

CALCULATION OF LOAD REQUIREMENTS

The design objective is to determine the capacity of the air-distributing equipment to balance the performance of the heat- and moisture-producing factors. The summer load requirement is most frequently the controlling load-determining factor, since winter requirements are invariably smaller. Determination of the summer load calculations are somewhat involved owing to the variable contributing load factors, the maximum effect of which may not occur simultaneously. Considerable judgment must be used to determine the various load relationships, *e.g.*, the heat-transmission difference between day and night, fluctuations in solar-heat load, lighting loads within the building, monitor construction or saw-tooth type, intermittent machinery operation for design heat-load requirements, and load location within the conditioned space. The air-conditioning system must be so designed that variable load factors will not affect maintenance of desired atmospheric conditions.

The summer internal heat load is determined by calculating the heat load produced from five major factors:

1. Heat transmission through the building structure
2. Solar-heat transmission
3. Heat produced by occupants
4. Heat produced from the lights
5. Heat produced from motors, steam, and all other heat-producing sources

The classification of heat loads (page 1476) all affect the sensible-heat gain within the treated space. There are other factors to be considered, such as the latent-heat gain caused by increasing the moisture content within the conditioned space.

Outside Design Conditions

The outside design atmospheric conditions vary for different geographical locations. The Weather Bureau records show that maximum summer dry-bulb and wet-bulb temperatures occur for a relatively short duration, usually in midafternoon. The peak transmission heat load on a building has a delayed effect, time lag, owing to the residual heat stored within the massive weight of the building structure. The practical design dry-bulb- and wet-bulb-temperature conditions, taking into consideration peaks and prevailing-wind velocities, are given in Table 21-6.

Table 21-6 is applicable for industrial process air-conditioning systems when refrigeration or chilled water is required to maintain specified conditions. For evaporative cooling and humidifying systems not requiring refrigeration, the design is based on the maximum outside wet-bulb depression for that particular geographical location; therefore, the dry-bulb temperatures given in this table should be used. To obtain the maximum wet-bulb depression, refer to the local United States Weather Bureau for that geographical location.

Heat Transmission. The heat transmission through the building structure is computed by determining the area of each type of room surface—walls, windows, partitions, floors, ceilings, or roof. Having determined the area on which transmission heat gain is to be figured, multiply each type of construction surface by its proper coefficient of transmission to obtain the Btu per hour per degree difference. The sum of all the transmission factors, when multiplied by the temperature difference between outside and inside design dry-bulb temperatures, will give the total Btu per hour.

Heat-transmission coefficients common to mill- or plant-type construction are given in Table 21-7.

Table 21-7. Heat-transmission Coefficients of Building Materials*

NOTE: Coefficients are expressed in Btu per hour per square foot per deg F difference in temperature between the air on the two sides and with still air on both sides (no wind).

Ground Floors. Until more complete data are available, it is recommended that a coefficient of 0.10 be used for all types of concrete floors on the ground, with or without insulation. For basement walls below grade, use the same average coefficient (0.10).

For basement walls below grade, a ground temperature of 32°F is recommended. For basement floors below grade, a ground temperature of from 40 to 55°F, depending on geographic location, should be used.

Table 21-7. Heat-transmission Coefficients of Building Materials* (Cont.)

Roofs

Flat roofs, concrete and frame construction

Flat roofs covered with built-up roofing		Without ceiling, underside roof exposed			With metal lath and plaster ceilings		
Type of roof deck	*Thickness of roof deck, in.*	No insulation	½-in. rigid insulation	1-in. rigid insulation	No insulation	½-in. rigid insulation	1-in. rigid insulation
Precast cement tile	1⅝	0 84	0.37	0.24	0.43	0.26	0.19
Concrete	2	0 82	0.37	0.24	0.42	0.26	0.19
	4	0.72	0.34	0.23	0.40	0.25	0.18

NOTE: Coefficients are expressed in Btu per hour per square foot per deg F difference in temperature between the air on the two sides and with a wind velocity of 15 mph.

* Reprinted by permission of the American Society of Heating and Ventilating Engineers, "ASH & VE Guide."

As a word of caution, when selecting an insulating building material, in surface contact with *humidified air*, the material must be impervious to the penetration of moisture.

Solar-heat Transmission. The solar-heat transmission, or sun effect, through building structures is difficult to determine owing to the periodic character of heat flow, variations in radiation, intensity on differently oriented surfaces, geographical location, and further effective time lag due to the mass of the building materials. The more generally accepted thesis is that the sun's rays will heat the outer surface of the walls and roofs and thereby give the same effect as an increase in temperature difference between inside and outside conditions. The sun's rays strike the roof nearly perpendicularly and strike the walls at various angles. Hence the roof surface is raised to a higher temperature than the walls. The effect of the sun's rays on glass differs in another respect. A small amount of heat energy is reflected, some is absorbed with slight rise in glass temperature, but the greater portion of the radiant heat energy passes through the glass and is absorbed on interior surfaces. This heat is quickly given up to the surrounding air, raising the temperature in the treated space. It is quite apparent that a barrier to solar heat's direct rays of the sun must be employed by means of awnings, white shades, paint, or blinds. Common mill practice is to paint the glass white. This presents an opaque nontransparent surface to reflect or absorb the radiant heat from the sun's rays.

There is some difference of opinion among recognized authorities as to how much of a heat load is imposed by the sun. However, one practical method, considered good engineering practice, is to calculate the sun effect separately by figuring 25°F increased temperature difference on roofs and 15°F temperature difference on walls for northern hemispheres and increasing these factors to 35°F on roofs and 20°F on walls in southern latitudes. In tropical climates these temperature differences would be further increased, and proper factors would be determined by the judgment and experience of the design engineer.

Heat Load from Occupants. The heat and moisture given off by persons vary with the activity of the individual and in a proportional degree are affected by the temperature and relative humidity. The total heat given off by a person is the sum of the sensible and latent heats and is practically a constant depending upon the activity of that person.

Table 21-8. Heat of Persons, Btu per Hour

Design room temperature	Activity *A* per person moving slowly			Activity *B* per person working rapidly		
	Sensible heat	Latent heat	Total heat	Sensible heat	Latent heat	Total heat
76	256	144	400	270	390	660
78	240	160	400	240	420	660
80	220	180	400	210	450	660
82	200	200	400	180	480	660
84	180	220	400	150	510	660

A practical basis of design in process air conditioning is to figure a heat-load factor of 500 Btu per hr total heat per person.

Heat Load from Lighting. Lighting is a usual source of heat generation in design calculations for process air-conditioning systems. The total lighting load requires analysis and good judgment to determine the effective lighting load factor. When considering a building with a saw-tooth or monitor roof, it is not necessary to figure both sun load and light load simultaneously. The greater of these two factors should be figured. Each watt of lighting consumed represents a heat load of 3.41 Btu per hr heat gain in the conditioned space.

Heat Load from Motors. The power generated by all machinery motors within the treated space is dissipated in the form of heat within that space. The engineering design must evaluate the motor-horsepower factor and connected horsepower within the treated space, *i.e.*, the total horsepower may be effective continuous operation, or the motors may operate intermittently. It is frequently permissible to figure less than the connected horsepower in operation at one time; on the other hand, it is advisable at times to increase the internal motor-horsepower load owing to overload operations. Electric motors are generally rated in units of horsepower output: 1 hp is equivalent to 2,545 Btu per hr. The following is a basis for calculating horsepower:

1. When motor and driving load are located within the treated space,

$$\text{Heat generated, Btu per hr} = 3.41 \times \text{watts input} = \frac{2545 \times (\text{actual brake horsepower})}{\text{motor efficiency}}$$

2. When motor is outside room and driving load is within the treated space,

$$\text{Heat generated, Btu per hr} = 2545 \times (\text{actual brake horsepower})$$

3. When motor is driving fan supplying air into the treated space through duct work, the heat equivalent in energy, applied to the air, is transmitted to the room.

$$\text{Heat generated, Btu per hr} = 2545 \times (\text{actual brake horsepower})$$

Customary practice is to add 10 per cent to the previously calculated sensible-heat load to provide for the fan-horsepower heat load. Then after the fan has been selected and actual brake horsepower determined, a back check is generally advisable.

Table 21-9. Motor Efficiency Ratings

Rating, hp	Efficiency average, per cent	Multiplying factor	Equivalent Btu/hp-hr
⅛–1	80	1.25	3170 (input)
1–10	85	1.18	3000 (input)
10 and above	88	1.14	2900 (input)

Other Heat-load-producing Factors. Heat-producing appliances, giving off heat, either sensible or latent heat, or both, must be determined and included in calculations. The generating sources may be uncovered steam pipes, hot surfaces, gas-fired heaters, electric generators, steam-heated cylinders, or open vats giving off moisture to the treated areas. All must be carefully analyzed and the heat produced taken into design calculations, or else these heat sources must be hooded and heat or moisture exhausted to atmosphere.

It is obvious from the foregoing discussion that the determination of the heat-load calculation is rather complicated by reason of the variable character of the contributing load components. A careful survey of the legitimate sources of heat loads will reveal in practice that it is not necessary to lump together "ignorance" and add safety factors sufficient to increase the apparatus and equipment capacity in exaggerated proportion to the economic actual requirements.

Ventilation. Ventilation requirements are determined as follows:

1. Sufficient fresh outdoor air is introduced into the room so that a slight static air pressure will be maintained within the conditioned space; losses are outward; there is no infiltration.
2. Sufficient fresh outdoor air to maintain adequate air for the occupants, keeping the dilution of obnoxious gases, when present, to the requirements of safety standards.
3. Sufficient fresh outdoor air must be provided to make up for air exhausted from manufacturing processes, in addition to requirement 1, to maintain a balanced air pressure within the treated space.

The estimation of fresh-outdoor-air requirements to maintain an air pressure within the treated area is generally calculated by the "air-change method," which is the determination of air leakage outward by roughly assuming a certain number of air changes per hour for each treated area, this assumption being dependent upon the type, use, and location of the building and whether it is an old wooden structure or a new modern brick or windowless type of building. This method, predicated upon actual experience records tabulated from many successful applications, has proved practical and reliable, thus eliminating the exhausting method of determining air leakage through doors and window cracks, with variable prevailing-wind pressures. This latter method may be used when more accurate and exact calculations are required.

Air-change Method. Air changes per hour under average conditions to maintain an air pressure within the treated room may be taken as shown in Table 21-10.

Table 21-10

Location and type (one or all four sides exposed)	Assumed air changes	
	Minutes per air change	Changes per hour
Old wooden-mill-type construction	30	2
Average mill-type construction	60–90	1–⅔
New brick modern or windowless building	120	½

To determine ventilation requirements, divide the cubical contents of the treated area by the assumed minutes per air change. This gives air-volume requirements directly in cubic feet per minute. Except in extreme cases, this air volume is generally sufficient and well above the cubic feet per minute per person required to meet the ventilation health standards for the occupants.

To determine ventilation requirements when obnoxious gases are present, refer to Table 21-11. The amounts and rate of production of the obnoxious gas are first determined, and then sufficient fresh outdoor air is introduced to keep the dilution concentration well within the standards of safety.

Air Purity. Dust suspended in air consists of solid particles of any material, all considered contaminative and generally most objectionable in process manufacturing. The control of air purity is one of the functions of process air conditioning. The control of dust consists of collection of the dust at the point of entry to the air-conditioning apparatus and the separation and elimination of the dust entrained in the air stream. The industrial dust problem is generally limited to solid particles larger than 10 microns. Thus this discussion will exclude fumes, smoke, and odors which are controlled by electric precipitation. Relative sizes of various dusts are shown in Table 21-12.

Industrial dust control has always been a problem in process manufacturing, and only in recent years has extensive research been conducted.

Dust problems may be classified as follows:

1. *Dust nuisance*—Causing damage to machinery, contamination, injury, or spoilage to product, and unclean working area.

2. *Fire and explosive hazard*—From any combustible dust which will oxidize rapidly or burn under certain concentrations; a potential hazard from explosion and fire.

3. *Occupational diseases*—Health of workers is impaired by various types of dusts and in most states the elimination of the hazard is required.

Dust varies in size, specific gravity, and shape. Size is the most important variable and is usually given as a mean diameter measured in microns or in screen sizes. A micron is one millionth of a meter, or 1/25,400 in. in size. Screen sizes are given in mesh or the number of openings per lineal inch of standard screen. Table 21-12 shows the U.S. Bureau of Standards standard test screens and their opening size in both microns and decimal parts of an inch.

Dust is rarely all of one size, and dust samples will be found to have a wide range of sizes, with the percentage of different sizes varying. It is thus impractical to specify a dust size by one number. The usual description of a dust includes the percentages of the dust in various size groups (either micron or mesh sizes). The determination of dust concentration or measurement of dust count is involved and many times rather complicated. Some of the methods of determining dust count are impingement on a prepared viscous surface, collection on filter paper, electric precipitation, and by direct analysis of samples by laboratory methods. The filter-paper method, by which air passes through filter paper for a known time period, is a convenient method of sampling, counting, and determining for analysis of the dust problem in process manufacturing.

Fire and Explosion Hazard from Dust. Dust explosions are caused by very rapid burning of air-borne dust, causing a rapid pressure rise. The explosion is generally the result of a limited concentration of dust in suspension in contact with some source of ignition. The resulting increase of pressure frequently dislodges large accumulations of dust within the building, resulting in secondary and more violent explosions. Thus the process air-conditioning problem is to prevent accumulations of inflammable dust in explosive concentration, to know rate of dispersion and the moisture content, and to determine the explosive pressure in known air concentrations. The minimum explosive concentration of air-borne dust generally ranges from 0.01 to 0.5 oz per cu ft, or 10 to 500 g per cu m. The industrial process air-conditioning engineer's problem primarily is dealing with hygroscopic dusts, moisture content, and elimination of static spark-ignition hazard by maintaining proper relative humidity within the treated space, thus prevent fire and resulting explosion.

Air Movement. The design of an industrial process air-conditioning system for ultimate effectiveness and efficiency depends upon an ample amount of air being circulated within the treated area to balance the internal heat-load gains. Since the treated or conditioned air is the mechanical carrier of heat and moisture to, or away from, process materials, sufficient air must be circulated and distributed uniformly in proportion to the load requirements encountered and varied with the variations of the heat load to maintain constant atmospheric conditions. The method of diffusing the air from supply outlets within the treated space is primarily a consideration of the material in process. Some products are very sensitive to direct air contact, suffering breakage or hardening of the surface, whereas other products require a direct air blast, *e.g.*, crystallization process. Types of supply outlets may be classified on a basis of outlet velocities, *e.g.*, low velocity (grille outlets), medium velocity (slotted outlets), and high velocity (nozzle outlets). The terms low, medium, and high are relative and vary with practical considerations of the problem involved. The higher the velocity, the greater the induction of room air.

Table 21-13. Relative Comparison of Supply-outlet Velocities

Velocity	*Fpm*
Low	Up to 600
Medium	600-1,200
High	Above 1,200

There are many variations of supply outlets—slotted grilles, fishtail diffusers, horizontal and vertical slots, and rectangular or circular nozzles. Their selection all depends upon practical experience and judgment in application to the particular problem under consideration. The ultimate decision and results to be obtained are to maintain uniform air conditions throughout the treated area without damage to the process materials, spoilage, delays, and resultant loss of labor. Conditioned air supply and diffusion are very important factors in process air conditioning. *No system is better than its air-distribution system.*

AIR CONDITIONING FIELD SURVEY

HEATING AND AIR CONDITIONING DEPARTMENT

Date DECEMBER 1, 1946
Prospect No. P 1036

Name JOHN DOE HOSIERY MILLS
Address GREENSBORO, N.C.

1. What manufacturing process is conducted in rooms to be conditioned. FULL FASHIONED SILK HOSIERY

1A. What are outside conditions.

	Dry Bulb	Wet Bulb	Relative Humidity
Highest Summer	96	72	
Lowest Winter	10		

2. What conditions do you want to maintain in
Summer—Temperature - °F Relative Humidity 60 %
Winter—Temperature 80 °F Relative Humidity 60 % See Also No. 33.

3. What floor is room on, top, intermediate or ground GROUND

4. What is the temperature in floors above and below in summer and winter.

5. What is temperature in rooms or space next to room to be conditioned, in summer and winter.
If this varies, indicate on sketch temperatures.
OFFICES - SUMMER SAME AS OUTSIDE; WINTER 80° DIRECT RADIATION

6. Give dimensions of room in feet 145 long 116 wide 15 high

7. Give kind of construction used in room in following table:

	Made of	How Thick	Inside or Outside
North Wall	BRICK	12"	OUTSIDE
South Wall	"	"	"
East Wall	"	"	"
West Wall	WOOD STUDS WITH 7/8" SHEATHING WOOL INSL 0.5		
Floor	CONCRETE ON DIRT		
Ceiling or Roof	3" WOOD PLANK, 1" CORK INSULATION, 5 PLY ROOFING		

8. Give number and size of windows in
North Wall 11- 6'x6' GLASS BLOCK
South Wall 13-6'x6' " "
East Wall 5- 6'x6' " "
West Wall 9-6'x6' DOUBLE GLASS
Are windows single or double glass AS NOTED

9 Give sketch on reverse side of this sheet showing exact arrangement of room. Show where space can be provided for our apparatus. Indicate points of compass on sketch.

10. What is your electric current—Alternating or direct AC
220 Volts 3 Phase 60 Cycle

11. What steam pressure 2 pounds. Is steam available at all times during the year NO
WINTER ONLY

12. Is the return system gravity or vacuum VACUUM

13. Do you heat conditioned room now NO What amount of direct radiation is installed. Indicate amount and location in sketch.

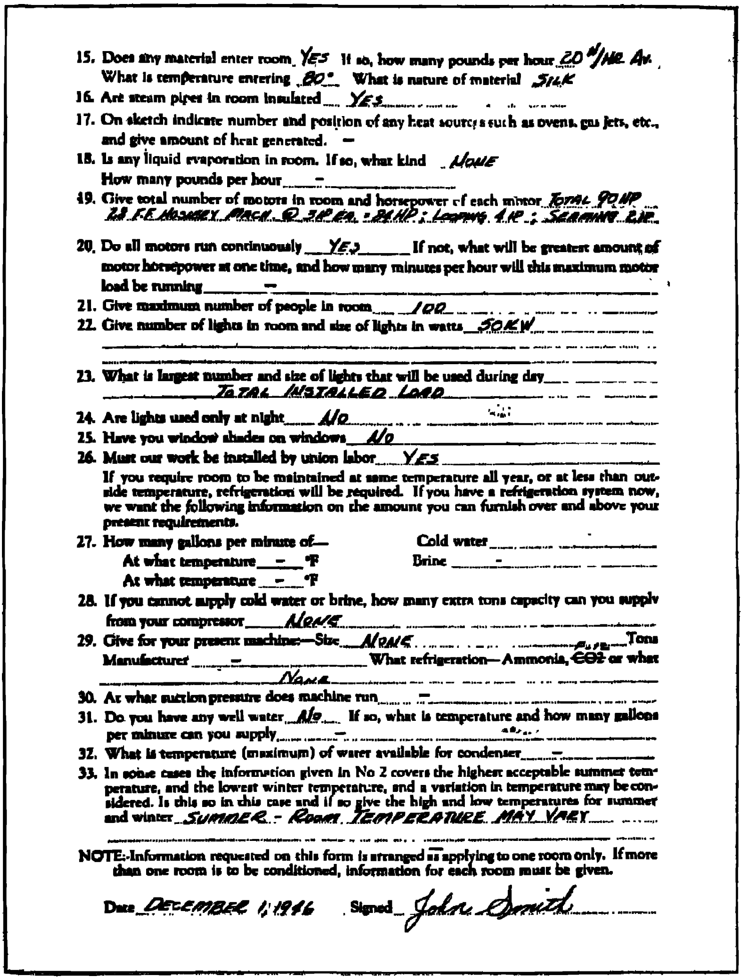
14. Do you have any ventilation or exhaust systems operating in conditioned room NO
If you have, how much air do they remove per minute

FIG. 21-14. Field survey, page 1.

The atmospheric conditions required in the treated area would be as follows:

1. *Summer*—Constant relative humidity, varying dry-bulb temperature
2. *Winter*—Constant dry-bulb temperature and relative humidity

Basis of Design. Refer to Figs. 21-14, 21-15, 21-16, and use these given factors as a basis of design. Then calculate the heat transmission through the walls, windows, and roof on a per-degree temperature difference (see Figs. 21-17, 21-18). Note that the outside summer atmospheric conditions are figured at the maximum wet-bulb depression because the transmission through the building will be the greatest under these conditions, thereby requiring the maximum air volume to balance the sensible-heat load. Remember the fact, as previously explained, that the summer requirements are the controlling factor in establishing air volume. Likewise, in the summer the fundamental law of saturation to spray-type humidifiers applies, *i.e.*, outside fresh air passing through a humidifier will *saturate* leaving the humidifier at the *entering wet-bulb temperature.* At saturation the dry-bulb and wet-bulb temperatures and dew point come together. Thus the leaving dew point (which is the same as the entering wet bulb) now becomes the dew-point temperature of the treated area. The air volume required to maintain the desired relative humidity, corresponding to that dew point, will be based on the sensible-heat rise from the dew-point temperature (also dry-bulb temperature) leaving the humidifier to the treated-area dry-



15. Does any material enter room YES If so, how many pounds per hour 20 #/HR. AV.
What is temperature entering 80° What is nature of material SILK

16. Are steam pipes in room insulated YES

17. On sketch indicate number and position of any heat sources such as ovens, gas jets, etc., and give amount of heat generated. —

18. Is any liquid evaporation in room. If so, what kind NONE
How many pounds per hour —

19. Give total number of motors in room and horsepower of each motor TOTAL 90 HP
28 F.F. HOSIERY MACH. @ 3 HP EA. = 84 HP; LOOPING 4 HP; SEAMING 2 HP.

20. Do all motors run continuously YES If not, what will be greatest amount of motor horsepower at one time, and how many minutes per hour will this maximum motor load be running —

21. Give maximum number of people in room 100

22. Give number of lights in room and size of lights in watts 50 KW

23. What is largest number and size of lights that will be used during day
TOTAL INSTALLED LOAD

24. Are lights used only at night NO

25. Have you window shades on windows NO

26. Must our work be installed by union labor YES

If you require room to be maintained at same temperature all year, or at less than outside temperature, refrigeration will be required. If you have a refrigeration system now, we want the following information on the amount you can furnish over and above your present requirements.

27. How many gallons per minute of— Cold water
At what temperature — °F Brine —
At what temperature — °F

28. If you cannot supply cold water or brine, how many extra tons capacity can you supply from your compressor NONE

29. Give for your present machine:—Size NONE Tons
Manufacturer — What refrigeration—Ammonia, ~~CO2~~ or what
NONE

30. At what suction pressure does machine run —

31. Do you have any well water NO If so, what is temperature and how many gallons per minute can you supply —

32. What is temperature (maximum) of water available for condenser —

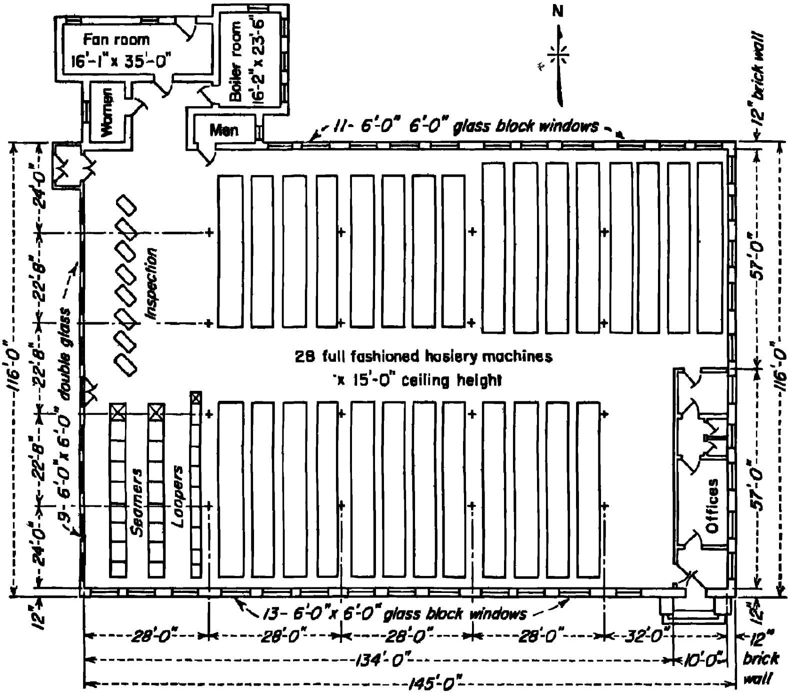
33. In some cases the information given in No 2 covers the highest acceptable summer temperature, and the lowest winter temperature, and a variation in temperature may be considered. Is this so in this case and if so give the high and low temperatures for summer and winter SUMMER - ROOM TEMPERATURE MAY VARY

NOTE:-Information requested on this form is arranged as applying to one room only. If more than one room is to be conditioned, information for each room must be given.

Date DECEMBER 1, 1946 Signed John Smith

FIG. 21-15. Field survey, page 2.

bulb temperature. The design for this load factor in the summer requires all outside fresh air through the humidifier for cooling by evaporation, thereby providing ample ventilation; in fact, pressure-relief dampers in the outside walls must be furnished to release this air to atmosphere. The relative humidity in the treated area will remain a constant, but the inside dry-bulb temperature will vary with the outside wet bulb. The reason that the relative humidity remains a constant is based on the *psychrometric phenomenon*, that, for a given relative humidity, there is practically a constant wet-bulb depression within the operating range of atmospheric conditions generally encountered in industry. The winter operation functions the same as for summer, except as the outside wet-bulb temperature drops below the winter dew-point temperature, air is automatically recirculated from the treated area, with a higher wet-bulb temperature, to the inlet side of the humidifier, so that the wet bulb of the mixture will maintain a constant winter dew-point temperature leaving the humidifier. Winter ventilation is adjusted to a minimum based on the air-change method. Generally the heat in the return air from the treated area is sufficient, so that no fresh-air heaters are required. In the summer, the atmospheric conditions in the treated area are maintained by varying the volume of supply air by means of a hygrostat, thereby controlling constant relative humidity. The dry-bulb temperature varies with the outside wet bulb. In the winter, the atmospheric conditions in the treated area are maintained by controlling the dew-point temperature leaving the humidifier and the dry-bulb temperature of the room. Thus the corresponding relative humidity and wet bulb are maintained.



Plan 1st floor

FIG. 21-16. Field survey, page 3.

The evaporative cooling (cooling by evaporation), humidifying, heating, and ventilating system is applicable to many types of industrial products in process of manufacture where relative humidity is the controlling factor.

EXAMPLE 2: Cooling, dehumidifying, humidifying, heating, and ventilating system, requiring refrigeration.

The atmospheric conditions required in the treated area would be as follows:

1. *Summer*—Constant dry-bulb temperature and relative humidity
2. *Winter*—Constant dry-bulb temperature and relative humidity

Basis of Design. Assume the same given factors as in Example 1, except that the summer inside dry-bulb temperature must not exceed 80°F, in other words, constant year-round atmospheric conditions, in the treated area. Since the heat transmission was calculated on a per-degree difference, the same calculations will apply, corrected for the temperature difference between outside and inside conditions (see Example 2 and Fig. 21-19).

Form 6019

Fig. 21-17. Typical calculations of an evaporative cooling and humidifying system—no refrigeration. Example 1, page 1.

Mechanical refrigeration cools chilled water which is sprayed in the air washer, termed the dehumidifier. Air is drawn through, thereby cooling the leaving air to saturation at the designed dew-point temperature required for the treated space or slightly below to allow for latent-heat gain within the conditioned space. The air volume is determined as before, *i.e.*, figured on the sensible-heat rise between the dry-bulb temperature leaving the dehumidifier and the conditioned-room dry-bulb temperature. To economize on refrigeration, the outside air is calculated on the minimum requirements sufficient to maintain an air pressure within the conditioned space and consistent with proper ventilation standards. The refrigeration load calculations are the sum of the total sensible heat plus the latent-heat

load and the heat of the outside air from the outside wet-bulb temperature to the inside wet-bulb temperature. When the latent-heat load within the treated areas is high in proportion to the sensible-heat load, correction in the dew-point temperature leaving the dehumidifier must be calculated to compensate for the moisture gain within the conditioned space.

The above methods of calculation are applicable to many types of industrial-process products of manufacture, where both the dry-bulb temperature and relative humidity are the controlling factors. When the characteristic properties of the process materials require control of dry-bulb temperature and relative humidity within limiting variations, direct-expansion or chilled-water cooling coils may be used in place of the spray-type dehumidifier.

Fig. 21-19. Typical calculations of a cooling, humidifying, and dehumidifying system with refrigeration. Example 2.

Design of Supply Ducts. To apply fans correctly and economically to process air-conditioning systems, it is necessary to understand what governs system losses, since the total system resistance solely determines the point at which a fan will operate on its characteristic curve. The system losses in general are caused by two distinct factors—frictional losses from viscosity action of the air and losses from accelerations and decelerations of the air stream. The trade commonly uses various terms to specify system resistance, total-pressure loss, and static-pressure loss. Fan performances are selected from performance curves or tables on fan total pressure or fan static pressure, the latter being the most common. The procedure to determine the static pressure of a system is as follows:

1. Sum up all component total-pressure losses of the parts of the system, including the fresh-air inlet, apparatus, and equipment, losses in ductwork, and velocity pressure at the discharge outlets of the system.
2. Deduct the fan-outlet velocity pressure (determine from a preliminary fan-size selection).
3. Pick a fan for the resulting static pressure.

The system design in practical application is to keep the total static pressure to a minimum (approximately 1 to 1½ in. static pressure), thereby economizing on operating-horsepower requirements. The frictional-resistance losses through apparatus and equipment are generally given in catalogues and published literature of equipment manufacturers; however, the pressure losses in supply ducts must be calculated.

Pressure Losses in Supply Ducts. The conventional engineering procedure in calculating duct friction loss is based on "equivalent round-duct pipe sizes" and a loss, equal to one velocity pressure, in a duct length equal to a stated number of pipe diameters. In practice, the number of pipe diameters for the loss of one velocity pressure varies from 40 to 70, depending upon the caution and experience of the individual making the calculations. There is little doubt that the figure 40 is exceedingly safe and that the allowance of one velocity pressure loss in 70 diameters is sufficient for a duct of good commercial workmanship. This explanation means that the losses in ducts are calculated in terms of velocity pressure of flow (in inches of water). Thus a friction loss in pressure in 70 diameters of length of duct is equivalent to the velocity pressure in inches of water.

This procedure assumes that the friction loss varies as the square of the velocity, and the standard table values for equivalent round ducts are based on this assumption. Experiments have proved that this assumption is too high and may safely be reduced. Having determined the pressure loss, tables may be prepared on a basis of "equalization for constant friction," which means the friction pressure loss in inches of water (gauge) per 100 ft of duct remains a constant. The layout and design of a duct system requires that the over-all duct resistance be kept as low as practicable within reasonable limits. In practical application, this method enables the engineer to select his total duct resistance and design the system to operate within those limits.

The formulas for round ducts have been thoroughly tested and may be used with safety. The whole concept of transferring these results to "rectangular-duct-size equivalent" is a fallacy unless used with reasoned caution. There are no engineering data that give the length (one velocity pressure taken for round ducts as 70 diameters) and the equivalent length for rectangular ducts since the cross section and perimeter may vary. Therefore, while the physicist labors for greater exactness, the engineer must design with the material at hand and use sound judgment.

Good engineering practice suggests procedure as follows:

1. Table 21-14 may be used, assuming the finest sheet-metal workmanship.
2. For rectangular ducts, the aspect ratio (*i.e.*, the long side to the short side) should not be greater than 1½ times the equivalent round-duct size.

EXAMPLE: In the use of Table 21-14, assume that the supply-duct design was limited to 0.4 in. static pressure and that the longest run of duct was 200 ft. Then the equalization for constant friction for 100 ft would be one-half 0.4 in. static pressure, or 0.2 in. static pressure. Allowing caution for workmanship, refer to the column headed 0.18 in. static-pressure loss. This column gives the carrying capacity in cubic feet per minute of air for round ducts for diameter shown on the right. The corresponding "rectangular equivalent" ducts, having the same pressure loss per unit length when carrying the same volume, cubic feet per minute, and having the same density, are shown in the columns on the right.

The above conventional procedure, therefore, has very great virtues of consistency, simplicity, and practicability in sizing of duct systems, and experience has proved the accuracy of this method.

TYPES OF PROCESS AIR-CONDITIONING SYSTEMS

The fundamental factors governing the type or selection of apparatus depend upon the characteristic performance of the apparatus and equipment best suited to meet the psychrometric characteristics of the process material. Therefore, a knowledge of the assembled arrangement of various types of equipment is essential. The general classifications of types of air-conditioning systems are "unitary" and "central station." Since the functions of unitary and central-station systems are the same, the dividing line is somewhat arbitrary. In general, however, a unitary system means factory-built and -assembled equipment, shipped complete as a unit to perform some specified function, *e.g.*, "humidifying unit." The central-station type of system may be defined as factory-built functional apparatus, assembled, erected, and fabricated in the field in a large plant centrally located to perform some specified functions.

Unitary System

Unitary apparatus is designed for horizontal- or vertical-assembly arrangement, for ceiling or floor mounting, the capacity being governed by the practical size, within reasonable limits of dimensions, weight, and convenience of handling and shipping. Generally, in process air conditioning, the unitary system is applicable to the smaller installations, as the name "unit" implies.

Central-station Systems

Central-station systems are classified in accordance with the function performed, *i.e.*, evaporative cooling, cooling, humidifying, dehumidifying, heating, and ventilating. The comparative effectiveness of the type of system selected depends upon the sensitivity of the process material to atmospheric conditions. Some process materials require close control of atmospheric conditions throughout the year, whereas other materials may permit variations of either dry-bulb temperature or relative humidity within stipulated limits. The general types of equipment for central-station systems may be modified to effect greater flexibility, improve performance, provide accurate control of conditions, or effect greater economy of operation without affecting the fundamental basic functions. Some types of equipment are applicable to all types of systems, whereas some equipment has a limited application.

The most commonly encountered types of central-station systems for process air conditioning are outlined in the following paragraphs.

Systems Not Requiring Refrigeration. For systems not requiring refrigeration, use an evaporative cooling system, the functions of which are cooling by evaporation, humidifying, heating, and ventilating. The atmospheric conditions in the treated area would be as follows:

1. *Summer*—Constant relative humidity, varying dry-bulb temperature, cooling by evaporation, ventilation
2. *Winter*—Constant dry-bulb temperature and constant relative humidity, heating, and ventilating

Systems Requiring Refrigeration with Spray-type Dehumidifier. For systems requiring refrigeration with a spray-type dehumidifier, use a dehumidifying cooling system, the functions of which are cooling, dehumidifying, humidifying, heating, and ventilating. The atmospheric conditions in the treated area would be as follows:

1. *Summer*—Constant dry-bulb temperature and constant relative humidity, cooling by chilled water, refrigeration, and ventilation
2. *Winter*—Constant dry-bulb temperature and constant relative humidity, heating, and ventilating

System Requiring Refrigeration with Direct-expansion or Chilled-water Cooling Coils. For a system requiring refrigeration with direct-expansion or chilled-water cooling coils, use a surface dehumidifier, the functions of which are cooling, dehumidifying, heating, and ventilating. The atmospheric conditions in the treated area would be as follows:

1. *Summer*—Slight variations of dry-bulb temperature and relative humidity within reasonable limits; cooling by direct-expansion or chilled-water cooling coils, refrigeration, and ventilation
2. *Winter*—Constant dry-bulb temperature, with special provision for humidifying when required, heating, and ventilating

Proper relationship between equipment selected and the internal heat load must be obtained because the cooling-load maximum capacity may operate at a small percentage of the year, and the winter heating load may operate under design conditions only a few days of the year or during shutdown periods. It, therefore, is essential that good partial-load performance be obtained for low operation costs.

Functional Equipment for Central-station System (without Refrigeration). *Evaporative Cooling System.* The evaporative cooling system cools by evaporation, humidifies, heats, and ventilates. This type of system is used with hygroscopic materials requiring close control of relative humidity and varying dry-bulb temperature within specified limits.

The functional equipment for an evaporative cooling system includes

Supply fan, motor, and drive
Humidifier, air-washer spray type
Humidifier pump and motor
Preheating, reheating, booster heating coils
Hot-water heater or steam ejector
Air-cleaning equipment, filters, or precipitators
Automatic controls

This equipment is fabricated with

Casing connections and ducts, normally of sheet metal
Piping—water, steam, air
Electric wiring

In Fig. 21-20 are shown fans of the backward-curve blade type, self-limiting horsepower characteristic. These fans are particularly suitable for industrial applications where high efficiency and reduced power are essential.

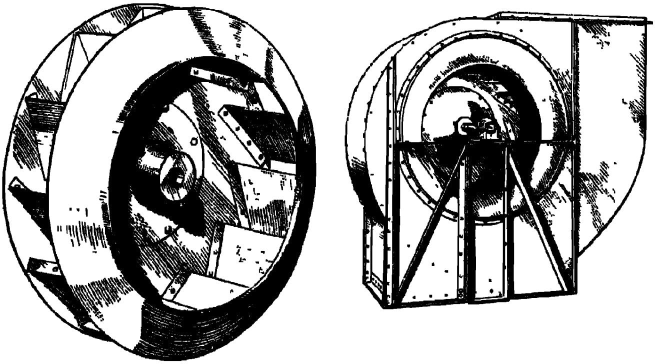

FIG. 21-20. Silentvane fan of the backward-curve blade type.

The humidifier shown in Fig. 21-21 is of the air-washer spray type. It cleanses, purifies, humidifies, and saturates the air that passes through. It is also suitable as a dehumidifier. It is suitable where precise control of humidity and cooling by evaporation is required. Velocities of 500 fpm are recommended.

The filter-washer type of humidifier (Fig. 21-22) is especially adaptable for humidifying and evaporative cooling and employs a bank of mineral-wool or glass-fiber filter pads in conjunction with water sprays to clean, humidify, and saturate the air with an extremely high degree of efficiency. It will remove dust, dirt, and solids down to micronomic fineness. The high efficiency is accomplished by spraying water against a bank of filters so positioned as to offer minimum resistance to air flow with a minimum amount of water recirculated. Thus a substantial saving in fan and pump operating horsepower is effected. Velocities of 700 fpm are recommended.

A sketch of an evaporative cooling system, general arrangement, is shown in Fig. 21-23, Arrangement 1.

Functional Equipment for Central-station System (with Refrigeration). *Dehumidifying Cooling System.* The dehumidifying cooling system cools, dehumidifies, humidifies, heats, and ventilates. This type of system is used with process materials requiring precise control of dry-bulb temperature and relative humidity at all times.

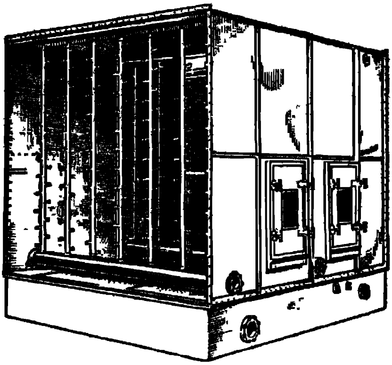

Fig. 21-21. Air-washer spray type—humidifier or dehumidifier with entering baffles removed.

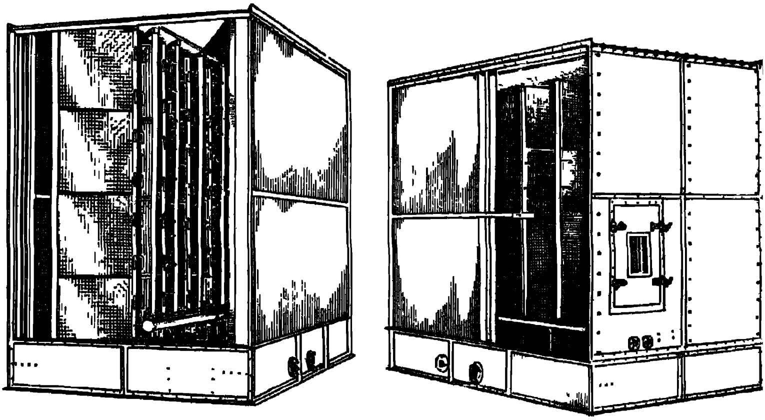

Fig. 21-22. Filter-washer—humidifier with side casing and entering eliminators removed.

The functional equipment for a dehumidifying cooling system includes

- Supply fan, motor, and drive
- Dehumidifier, air-washer spray type, spraying chilled water, well water, or with direct-expansion cooling coils or chilled-water cooling coils located in the spray chamber
- Dehumidifier pump and motor
- Preheating, reheating, booster heating coils
- Hot-water heater
- Air-cleaning equipment, filter, or precipitators
- Automatic control

Refrigeration system—compressor, with motor, condenser, water chiller, and all auxiliary equipment

This equipment is fabricated with

Casing connections and ducts, normally of sheet metal
Piping—water, steam, air
Electric wiring
Supply fans (see page 1500)
Dehumidifier (see page 1501)

The dehumidifier air washer is similar in detail in all respects to the humidifying air washer, except that a greater volume of recirculated water is required for cooling.

Refrigeration System

The function of the refrigeration system is to cool and dehumidify the air supplied to the treated area. The methods, arrangement, and design have so many ramifications that the subject is covered thoroughly in Sec. 9.

Other types of functional equipment applicable to dehumidifying and cooling systems for process materials include

Refrigeration compressors (Fig. 21-26)—The compressor illustrated is hermetically sealed with a refrigerant-cooled motor. It is designed for Freon-12 refrigerant for use in air-conditioning and industrial refrigeration applications requiring suction evaporating temperatures ranging from 10 to 50°F.

Water-cooled condenser (Fig. 21-27)—The water-cooled condenser is of the shell-and-tube type with the water tubes constructed with integral copper fins for high capacity. Water headers are removable for inspection and cleaning of the tubes.

Aquamiser (evaporative condenser) (Fig. 21-28)—The Aquamiser is a Freon-12 condenser which, in a single, compact, economical unit, combines the desirable features of a water-cooled condenser, an air-cooled condenser, and a cooling tower.

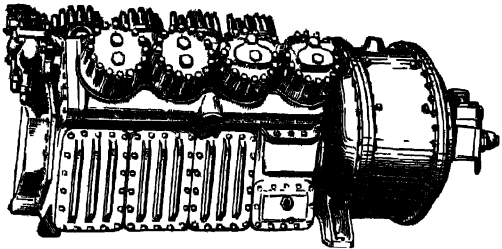

FIG. 21-26. Westinghouse hermetically sealed Freon compressor with refrigerant-cooled motor.

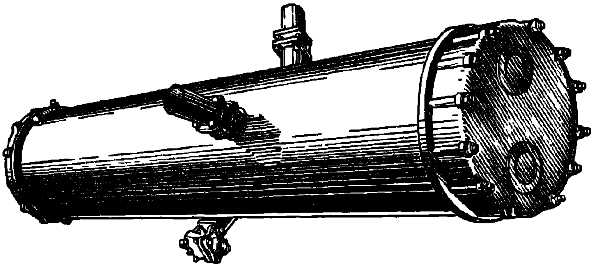

FIG. 21-27. Water-cooled condenser—shell- and tube-type.

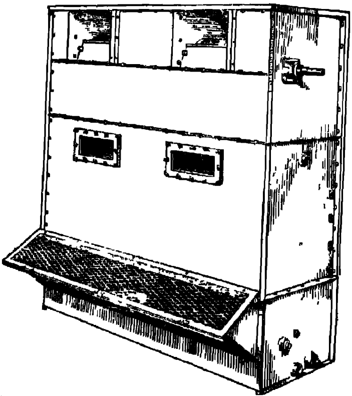

FIG. 21-28. Aquamiser—evaporative-condenser type.

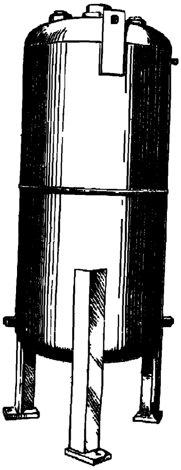

FIG. 21-29. Water-chilling unit—vertical type

It is used instead of a water-cooled condenser where condenser water in sufficient quantity is not available, or its use is restricted. It is more economical in first cost and operating cost than a cooling tower used in conjunction with a water-cooled condenser.

Water-chilling units (Fig. 21-29)—The water-chilling unit illustrated in Fig. 21-29 is a semiflooded type of Freon-12 vertical design. Water is circulated through the coil tubes which are cooled by refrigerant gas evaporating around the outside of the tubes within the steel shell.

Central-plant-type unitaire (Fig. 21-30)—Central-plant-type air conditioners (unitaires) are completely self-contained, with all the component parts of an air-conditioning system, and are designed especially for installation with supply and return air ducts. The compressor is hermetically sealed, direct connected, equipped with 50 per cent unloader, with water-cooled condenser, direct-expansion Freon-12 cooling coils, supply fan, motors, and drive equipped with complete automatic control.

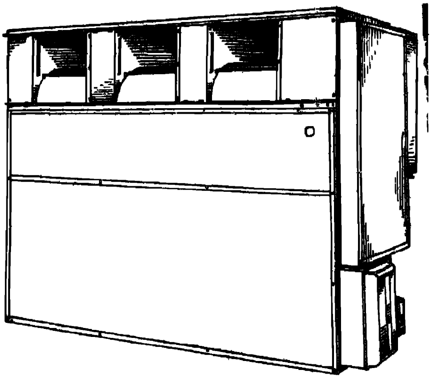

Fig. 21-30. Unitaire air conditioner—central-plant type.

Surface dehumidifier (Fig. 21-31)—The surface dehumidifier is designed with either direct-expansion or chilled-water coils placed directly in the air stream with spray water directed against the coils on the air-entering side. The spray water is carried through the coils so as to wet the entire surface. This arrangement keeps the coils clean and results in practically saturated air leaving the coils. The surface dehumidifier is applicable for process materials where the finesse and accuracy of the dry-bulb temperature and relative humidity are not so essential as in arrangement 2 (Fig. 21-24), slight variations being permissible.

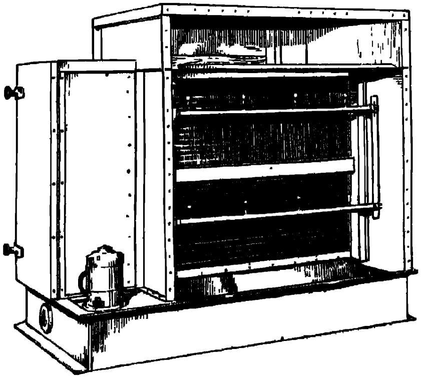

Fig. 21-31. Surface dehumidifier, entering end, with cooling coils and recirculating water pump.

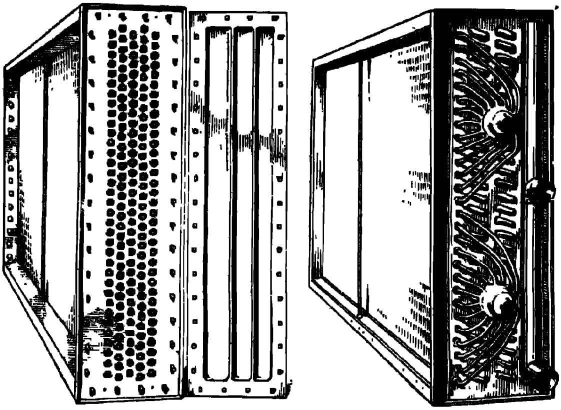
Direct-expansion and Chilled-water Cooling Coils. Diagrammatic sketch of apparatus for arrangement 3 (Fig. 21-25) will be the same as for arrangement 2, except that direct-expansion or chilled-water coils are substituted in place of dehumidifier air washer. Direct-expansion cooling coils have distributing headers giving equal refrigerant distribution to all circuits, whereas the chilled-water cooling coils employ two types: (1) with tubes individually assembled into the headers to permit cleaning and (2) with continuous tubing (see Fig. 21-32).

Arrangement 3 is applicable for process materials requiring control of the dry-bulb temperature within limiting variations and low relative humidities varying but not exceeding prescribed limits.

The preceding arrangements of central-station systems with refrigeration may be varied in design to suit different manufacturers' equipment with many ramifications. The essential fact, however, is that the degree of accuracy of maintaining the atmospheric conditions desired will be governed by the process material and the selection of functional equipment. The degree of accuracy in maintaining precise atmospheric control will be in the order of: (1) spray-type air washer; (2) surface dehumidifier; (3) direct-expansion or chilled-water cooling coils. Each type of functional equipment has a logical application solely judged by the characteristic properties of the process material in sensitiveness to atmospheric conditions.



Chilled-water cooling coils—continuous-tube type with header removed.

Fig. 21-32.

CONCLUSION

Industrial process air-conditioning engineering today is one of the most specialized fields of engineering and is indispensable to modern industry. Thousands of manufacturers in hundreds of industries in ever-broadening fields have benefited from the practical application of the fundamental laws and underlying principles of this new and exacting science. Industries whose products in process of manufacture are affected by changing atmospheric conditions demand climate made to order, which means increased production, better quality, ample ventilation, clean, improved, healthful, and comfortable conditions for workers. It improves personal efficiency and results in less loss of time, less labor turnover, and greater profits to the manufacturer. Industrial process air conditioning has progressed to be a large and well-established industry, accepted by the leading and progressive manufacturers as a basic necessity.

PNEUMATIC CONVEYING, DUST CONTROL, AND FUME EXHAUST

BY HOWARD M. NICHOLS

Assistant Manager, Industrial Department, Westinghouse Electric Corp., Sturtevant Division

PNEUMATIC CONVEYING

There are three general types of pneumatic conveyors: low-velocity air conveyors, high-velocity air conveyors, and pneumatic-tube conveyors.

Air conveyors of these types are adapted to the conveying of bulk materials and find their widest field of usefulness in those situations where mechanical conveyors are restricted because of structural difficulties, lack of room, or excessive first cost compared with the quantity of material to be conveyed. The characteristic advantages of air-conveyor systems are usually lower initial cost than mechanical conveyors (where moderate quantities of material are to be carried a considerable distance), low maintenance expense, and a flexibility of plant whereby all obstacles such as roads, rivers, railroads, buildings, machines, etc., can be overcome without difficulty. The air conveyor will shoot the material around corners, up or down, anywhere the pipe is laid. Other advantages are automatic features, economy in labor, elimination of spillage, elimination of dust and its harmful effect on employees and machinery alike, protection of the conveyed material from exposure and loss while in transit, reduction of accident and fire hazards, reduction of the number of moving machine parts, and the concentration of these parts at some convenient place where they can be most easily taken care of. Balanced against these many advantages are the facts that air conveyors usually consume more power than mechanical conveyors and are restricted in the types and sizes of materials that can be conveyed. As an illustration, sticky materials, friable materials, and materials containing large and heavy lumps are types best handled by other methods. However, air conveyors are successfully handling a wide variety of materials ranging in size from sawdust to wood chips and blocks and in weight from feathers to metal chips. However, air conveyors are limited to the handling of bulk materials, and they are also restricted to such materials as will pass through the piping system without clogging and to such materials as can be readily separated from the conveying air at the discharge end.

Air-conveying systems of both the low- and high-velocity types include the following elements: an air mover which may be a centrifugal fan; centrifugal compressor, or positive-pressure blower; a conveying pipe; a feeding device or suction nozzle; and finally a discharge device where the material is separated from the conveying air. The discharge may be an open end of pipe, a screened bin, a cyclone separator, or a rotary valve or air locks.

Low-velocity Air Conveyors. Low-velocity air conveyors are usually of the fan type and are particularly adapted to handling light bulky materials such as raw cotton, wool, wood shavings, sawdust, shoddy, cut rags, waste paper, rubber scrap, jute, hemp, granulated cork, asbestos, leather buffings, cast-iron chips and borings, crushed-steel chips, aluminum chips, and brass chips. Materials which have a tendency to stick in the conveyor pipes or fans and materials which are easily damaged require special care in the application of pneumatic conveying. Also, hygroscopic materials such as salt and raw sugar and such materials as silk, rayon, unscoured grease wool, and wool heavily loaded with oil emulsions all have a tendency to adhere to the pipe and fan. Fan wheels which have cone backs of smooth construction and which are free from crevices and fins are required to convey cotton, wool, paper trimmings, and similar materials through the fan. Special care is required to have close fits between the arms and blades of the fan as materials of this type will catch in any crevice and build up until the air passages are blocked. In the trade this type of fan wheel is known as a "wool wheel" and is furnished of cast iron, cast bronze, or structural steel. Naturally, the cast wheels are preferable from a smoothness standpoint, but fan speeds are often such that built-up steel wheels are required.

Materials can be conveyed equally well by a suction or a pressure system since the conveying effect is due to the air velocity or the carrying power of air in motion.

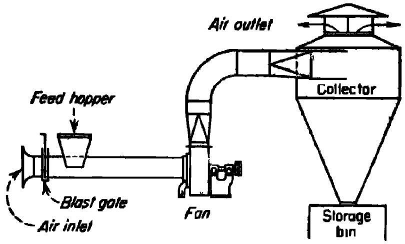

Fig. 22-1. Blow-through conveying system.

The most common and simplest type of air conveyor is the blow-through system (Fig. 22-1) where the material is fed into a hopper in the suction pipe and is then carried by the air stream through the fan and delivered, together with the conveying air, to the collector or separator. At this point, the material is separated from the air, the conveying air being discharged to the room or atmosphere, while the conveyed material is delivered to storage or process by means of a gravity spout. Materials such as wool and wastepaper are usually taken through the fan and blown directly into storage bins, which have the upper portion covered with coarse screen (¼- to 1-in. mesh) to allow the escape of the conveying air.

In draw-through conveying systems (Fig. 22-2), the fan comes after the collector, which consequently is under suction or vacuum and hence requires an airtight seal in the material discharge spout, usually provided by a rotary valve. If intermittent discharge is satisfactory, seal can be maintained by attaching to the discharge spout an airtight storage hopper with blast gates at top and bottom of hopper. Normal operation is with upper gate open and lower gate closed. Collected material is discharged without breaking the vacuum by closing the upper gate and opening the lower gate.

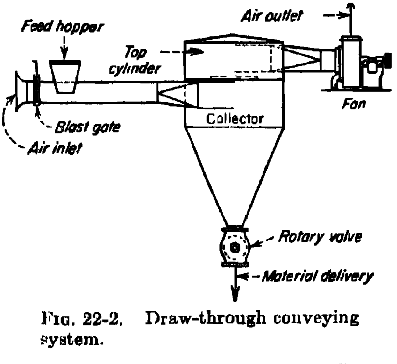

Fig. 22-2. Draw-through conveying system.

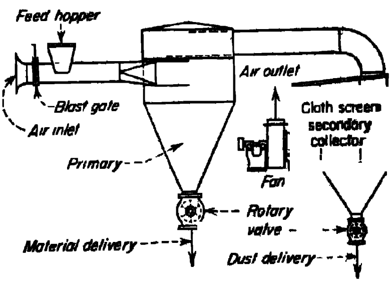

Fig. 22-3. Draw-through conveying system with secondary filter collector.

In the conveying of materials containing fine light dust particles which are to be removed from the conveyed material or which would constitute a dust hazard if discharged at the delivery end of a cyclone collector, the use of a secondary filter collector, as shown by Fig. 22-3; is required. This secondary collector may be a cloth-screen arrestor, electric precipitator, air washer, scrubber, or other comparable device.

In blow-through pressure-feeder conveying systems (Fig. 22-4) the material is fed into the air stream by means of an airtight rotary valve located in the discharge line near the fan outlet. As in the regular blow-through system, the material is discharged from the collector by means of a gravity spout.

Where materials cannot be passed through the fan and blow-through feeder or draw-through arrangements are unsuited to the material, an injector feeder (Fig. 22-5) may be used. Paper strips and wool are types of materials that are sometimes conveyed by the injector method. While the injector method is well adapted for conveying materials which cannot be successfully fed into the system by mechanical means and which cannot be handled through the fan, the mechanical efficiency is much lower than with any of the other types of air conveying. The power requirements are usually five times the power required by the conventional air-conveyor methods, and thus this system is limited to special cases where the advantages outweigh the drawback of greater power consumption.

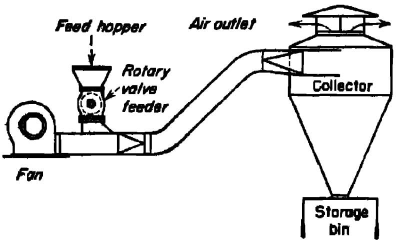

Fig. 22-4. Blow-through pressure-feeder conveying system.

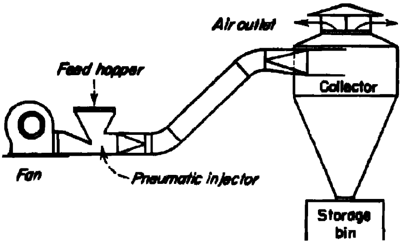

Fig. 22-5. Injector conveying system.

Air Requirements. Two factors are involved in the design of low-velocity air conveyors, *viz.*, necessary air velocity to keep the conveyed material in suspension and in motion in the air stream and quantity of air (cfm) necessary to move the given amount of material. Both the air velocity and the quantity of air per pound of conveyed material depend on the density and physical conditions of the materials If either the air velocity or quantity of air per pound of material falls below the minimum value, the material will start to settle out in the bottom of the horizontal pipe. and at the foot of the risers, and the system will soon plug and become inoperative.

Conveying velocities are dependent on a number of factors, the more important being the size and shape of the particles to be conveyed, the density of the material, and its surface condition.

The theoretical air velocity required to lift a smooth spherical particle is

$$V = 15{,}000 \left(\frac{G}{G+1}\right) \sqrt{d}$$

where V = air velocity, fpm
G = specific gravity of the material
d = particle diameter, in.

This formula is useful only in making a rough check of air velocity, since in practice conveyed materials are not spherical or of uniform size. However, it will be observed from the formula that the air velocity increases with an increase in density of the material and that it also increases with an increase in the particle size. This general relation holds for all types and sizes of materials.

Experience is the best guide in determining which air velocities should be used, or a similar system may be available for actual tests of air velocities and air volumes.

In practice, it is customary to make no distinction between the velocities required for vertical and horizontal transport of materials. It is usually desirable to maintain a minimum velocity of about 3,000 fpm.

Materials that are commonly conveyed by a low-velocity fan system usually have sufficient surface area to be successfully conveyed by the velocities given in Fig. 22-6. The curve in this illustration is based on one variable only, *i.e.*, the bulk weight of a cubic foot of the material in the condition in which it is to be conveyed. If this material happens to be chips with many voids in a cubic foot, the bulk weight will be much less than the density. Also if the material is of a sticky nature, special consideration must be given to the problem. If the material contains moisture, the total weight including the moisture is used in determining the air constants.

It will be noted that the conveying curve gives no consideration to the size of the particles, and for that reason, if there are unusually large pieces of material, a check of the theoretical conveying velocity should be made, assuming an equivalent sphere of the largest piece. Actual conveying velocity should be 50 per cent over this theoretical velocity, or curve velocity, whichever is greater.

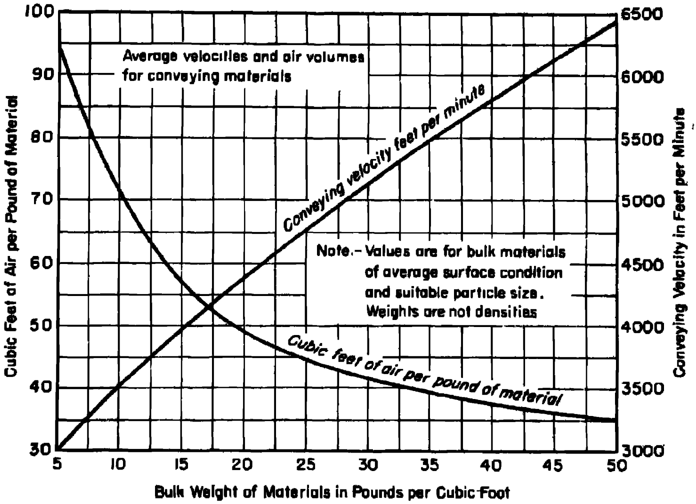

FIG. 22-6. Average velocities and air volumes for conveying material.

There is no theoretical approach to the determination of the amount of air required to convey a pound of material, and consequently it is necessary to depend upon experience and spot checks of existing systems. Experience has demonstrated that with low-velocity systems (3,000 to 7,500 fpm) the cubic feet of air required to convey a pound of material varies from approximately 90 ft of air per lb for light fluffy materials such as open cotton to around 35 to 40 cu ft of air per lb for heavy compact materials.

The curves in Fig. 22-6 are based on an even feed of material to the systems. If the feed is uneven, sufficient air must be provided to convey the maximum quantity of material which may be fed to the system during any short interval.

Within the range of low-velocity conveying, velocities higher than normal do not appear to have much effect on the quantity of air required per pound of material.

A special branch of low-velocity conveying is concerned with the removal of chips, sawdust, or other refuse material from production machines. The most prominent application is in woodworking plants where the machine cutters produce shavings and sawdust in such large quantities that, unless the waste material is removed by a suction system as fast as it is made, it soon clutters up the machines and surrounding floor space, thus necessitating frequent stops to clean the machines and clean away the refuse.

The design of refuse-removal systems for machines is usually governed by the requirements that sufficient suction and air exhaust must be provided around the cutter to draw the chips or shavings into the conveyor pipe. These conditions require excess air over the amount required to convey the material once it is gotten into the conveyor pipe. Similarly, if the conveyor pipes are not more than 20 to 25 per cent greater in area than the area of the pickup ducts, the required suction at the cutter hood usually results in sufficient conveying velocity.

In woodworking plants the size of connections serving the cutter hoods and the suction maintained at these connections will vary with the quantity of shavings made, kind of lumber, its condition, whether dry or wet, speed of the cutters, etc.

The suction required at the hoods varies from 2 to 5 in. of water, depending upon the type of plant, high- or low-speed machines, depth of cut, size of chips, and kind and condition of the lumber.

Two-inch water suction is sufficient for finish mills such as found in the East. Suction of 2½ to 3½ in. is used for heavy manufacturing, while heavy-duty planing mills manufacturing lumber on the Pacific coast use suctions up to 5 in.

In Table 22-1 are listed sizes of hood connections suitable for average conditions in finish mills, general manufacturing, and similar applications.

On very heavy-duty jobs it is desirable to check the air volume and velocities in accordance with the data for straight bulk conveying. This applies particularly to exhaust from hogs and relay systems.

High-velocity Conveying. High velocity or high-pressure pneumatic conveying has a much smaller field of economic application than the conventional low-velocity fan type and is used principally for the direct delivery of dry bulk materials such as soda ash, caustic lime, fullers earth, etc., from cars or boats to storage and process bins. Since the pickup nozzles can be arranged to be self-feeding, this method of conveying is particularly adapted to such materials as soda ash and the like which are extremely disagreeable to work around. Grain is also handled by high-velocity pneumatic systems, but since mechanical methods are more economical in power consumption, the high-velocity pneumatic systems find their principal fields of usefulness where special conditions control, such as unloading barges, picking up spills in grain elevators, etc.

In its simplest form, the high-velocity pneumatic conveyor consists of a positive pressure exhauster or centrifugal exhauster, a material collector or receiver, and the necessary conveying duct, terminating in a flexible hose with a suction nozzle for easy manipulation in the car or storage pile.

An important part of the equipment is the suction nozzle which should be light to allow for easy manipulation by the operator and should have some means of allowing a "free-air" inlet, making it impossible to choke the nozzle by burying the open end. It is an advantage to be able to regulate the free-air inlet according to the conditions existing with different materials.

The material collector usually comprises a centrifugal separator, into which the material is discharged and from which it is withdrawn through an air-lock rotary valve. Fines not separated centrifugally pass into a cylindrical bag filter having a number of compartments. The filter is arranged to offer a maximum of cloth filtering surface in proportion to the total area. The filters are usually cleaned by the automatic reversal of air flow through the cloth and the consequent partial collapse of the tubes. The air reversal is caused by the operation of slow-moving cams which control the opening and closing of the valves. In some types, compressed-air jets are also directed against the bags to assist in the cleaning operation. High-efficiency filters are a necessity since fines that could be passed through a fan and discharged to atmosphere must be excluded from positive-pressure blowers and centrifugal compressors.

In low-velocity conveying sufficient air must be introduced with the material so that the material is kept in suspension in the air stream. If this condition is not fulfilled, some of the material will collect in the bottom of the pipe and slowly build up until the systems become inoperative. Under these conditions the transporting power of the air appears to increase only moderately with an increase in air velocity above the critical velocity for the particular material involved. However, as the velocity is further increased, there appears to be an upper critical point, depending

Table 22-1. Exhaust-hood Connections
(Sizes of connections for woodworking machinery)

Machine	Type of application	No. of connections	Diameter of pipe, in.
Swing saws	Small size on dry-kiln lumber	1	4
	Large on wet	. .	4–6

on the characteristics and density of the material, where a given quantity of air will carry much more material. While this phenomenon is termed high-velocity conveying, the action appears to be a combination of moving the material in suspension together with pushing the material along in the pipe by the dynamic pressure of the high-velocity air.

There are practically no authentic published data covering velocity and air quantity required for high-velocity conveying of various material. However, it can be stated that the velocities range from 10,000 to 20,000 fpm and air volumes are one-fifth or less of those required for low-velocity conveying.

Pneumatic-tube Conveyors. The pneumatic-tube conveyor is a conveyor of small articles enclosed in a container which is built to fit the tube closely and which is forced through the conveyor tube by air pressure in a similar manner to the way the piston of a steam engine is pushed along by the steam pressure. Tubes are run between the points to be served, with a dispatch and receiving terminal at each end.

The tubes must be continuous, and preferably should be incased for protection against mechanical injury. Airtight joints and smooth interiors are absolutely necessary for successful operation.

The carriers in which the material to be conveyed is placed are made of metal or molded material covered at the ends with felt. The trailing end of the carrier is provided with a skirt of felt. The air pressure behind it forces it open, making a tight fit and preventing leakage of air past the carrier. The nose is usually provided with a felt buffer which also assists in maintaining an airtight condition.

Pneumatic tubes are worked either by pressure or vacuum. Pressures may range from 1 to 10 lb, and the vacuum system ranges from around a pound to several pounds vacuum. Air volumes depend on the design and tightness of the system. As an illustration, a well-designed single-station system using 2¼-in. tubes and operating on the vacuum principle would require around 50 cfm per station at 1 to 2 lb vacuum.

DUST CONTROL

Control of dust, gases, and fumes in industrial plants is governed in most states by law and supervised by state boards. Most of the basic laws are broad, delegating wide powers to the control boards to set up rules and regulations for the control of these hazards. New York State was a pioneer in this field, and many of the state codes are patterned after the New York code, although in some states there is considerable variation from the New York code, especially as to the suction required at grinding-wheel hoods. Usually definite and detailed specifications are given for the control of dust from grinding wheels and similar applications, while for other dust and fume hazards the rules are of a general nature, specifying that the noxious materials must be removed to a satisfactory degree and leaving the details of accomplishment to the designer of the system.

Where detailed codes are involved, the specific requirements must be followed. However, where there are no detailed code specifications, it is customary to follow the New York specifications in the design of grinding- and buffing-wheel exhaust systems.

The basis of the New York code consists of specifications covering the size of hood connections for given wheel sizes, together with the requirement that 2 in. of water suction must be maintained at the hood connections.

The New York code requirements (current at date of this publication) for minimum size of branch pipes for grinding and buffing wheels are as shown in Table 22-2.

Table 22-2. Branch Connections for Grinding Wheels

Diameter of wheel, in.	Maximum wheel surface, sq in.	Minimum diameter of branch pipe, in.
6 or less, not over 1 thick	19	3
Over 6 to 9 inclusive, not over 1½ thick	43	3½
Over 9 to 16, inclusive, not over 2 thick	101	4
Over 16 to 19, inclusive, not over 3 thick	180	4½
Over 19 to 24, inclusive, not over 4 thick	302	5
Over 24 to 30, inclusive, not over 5 thick	472	6

Where the maximum grinding surface exceeds 472 sq in., a proportion of 1 sq in. of pipe area to each 15 sq in. of grinding surface shall be provided for dust removal. Disk wheels of 24 in. or less in diameter shall be provided with branch pipes at least 4½ in. in diameter; wheels over 24 in. in diameter shall be provided with branch pipes not less than 5 in. in diameter.

If a wheel is thicker than those in Table 22-2, it shall have a branch pipe not smaller than is called for by its wheel surface in the proportion of 1 sq in. of pipe area to each 15 sq in. of grinding surface.

Table 22-3. Branch Connections for Buffing Wheels

Diameter of wheel, in	Maximum wheel surface, sq in.	Minimum diameter of branch pipes, in.
6 or less, not over 1 thick	19	3½
Over 6 to 12, inclusive, not over 2 thick	75	4
Over 12 to 16, inclusive, not over 3 thick	151	4½
Over 16 to 20, inclusive, not over 4 thick	251	5
Over 20 to 24, inclusive, not over 5 thick	377	5½
Over 24 to 30, inclusive, not over 6 thick	565	6½

If a wheel is thicker than those in Table 22-3, it shall have branch pipes not smaller than are called for by its wheel surface as specified.

Buffing wheels 6 in. or less in diameter used for jewelry work may have 3-in. branch pipe.

In grinding, polishing, and buffing auto bumpers, propellers, and other special work, more than one branch pipe from the hood may be necessary, according to the work being done. Similarly, on extremely wide face wheels where the amount of abraded material is comparatively small, a smaller sized branch pipe may be satisfactory.

The code requires that sufficient static suction shall be maintained in every branch pipe to produce a difference of level of at least 2 in. of water between two sides of a U-shaped water gauge. The point at which test is made shall preferably be 10 diameters of the pipe from the hood, but in no case less than 1 ft from the hood. The test is made by placing one end of rubber tube over a small hole made in the pipe, the other end of the tube being connected to one side of the water gauge. This test must be made with all branch-pipe connections open and unobstructed. Balancing devices which are placed on the upstream side of the test hole are not considered as obstruction. Test holes should preferably be drilled since a prick punch leaves an internal burr which is detrimental to accurate suction reading.

General Specifications for Piping. The area of the main suction pipe at any point shall not be less than the combined areas ("load areas") of the pipes joining it between such point and the tail end of the system, except that the area of main suction pipe used for removal of dust from grinding, polishing, and buffing wheels shall be not less than 20 per cent greater than the area of all pipes joining it. The area of floor sweeps, which are normally closed by blast gates, is not included in computing main pipe area.

For easy access to the fan, the length of pipe adjacent to the inlet should be a split sleeve approximately the same length as the diameter of the pipe, but not less than 18 in.

Pipe should be constructed of galvanized iron of not less than the gauges specified in Table 22-4. Elbows should be two gauges heavier than the corresponding straight pipe. For particularly abrasive conditions heavy black iron pipe may be required with elbows having replaceable backs. Where flexibility is required, telescopic pipe, ball joints, flexible metal hose, and reinforced rubber hose are used. Any pipe reinforcing should be made on the outside of the pipe.

All lap joints should be so constructed that the outlet of one length of pipe enters the inlet of the following length in the direction of air flow. All joints should be either lock-seamed, riveted, or spot-welded and in addition should be soldered airtight. Every branch pipe, except in special cases, should be connected at the top or side and at an angle not exceeding 45 deg and should be inclined in the direction of air flow at the junction with the main. Instead of entering the main at an angle shoe collars may be used since their resistance is about the same as a branch entering at an angle.

Increase in diameter of pipes should always be on a taper and not by an abrupt change. Branches should join the main in the tapered section. All pipes should be free from burrs, projections, and sharp edges. Unless space will not permit, every bend, turn, or elbow should be made with a center-line radius at least equal to twice the diameter of the pipe, and all horizontal pipes should be provided with cleanout doors spaced 10 to 20 ft apart and located near branches.

Where large chips or heavy pieces of solid material may be carried along with the air stream into the duct system, chip traps are advisable in the branch ducts, or they may be combined with the machine hoods. Chip traps which depend on air expansion for their effectiveness should have a cross-section area of at least eight times the area of the connecting duct.

Buffing- and grinding-wheel systems should be segregated since sparks from grinding wheels may set fire to the lint and grease from buffing operation if both are carried through the same duct system.

The duct system should not pass through fire walls or barriers. This can sometimes be avoided by placing the main ducts on the outside walls of the building. Many times vertical risers can be placed in stair wells to avoid piercing important floors. Insurance regulations require that, where ducts do pass through fire walls, they be provided with automatic fire dampers on both sides of the wall.*

Duct systems for the removal of explosive or inflammable materials should be kept independent of other duct systems. The ducts should be as straight as possible, should lead directly to the outside of the building, and should never pass through other rooms. Automatic-sprinkler heads should be provided near the inlet and outlet of the duct system. If installed inside the ducts, they should be placed in an offset and not in the direct path of the air flow. Explosion-relief vents are usually required on duct systems handling explosive or readily flammable materials. Such systems should also be electrically grounded.

---

* For details of fire dampers, see regulations published by National Fire Protective Association, Boston, Mass.

NOTE—Proportion dimensions to determine other sizes.

FIG. 22-7. Cyclone-collector dimensions.

The exhaust fan, often known in the trade as a planing-mill exhauster, should be suitable for handling material through the wheel, which requires that the blades be radial or forwardly pitched.

Dust collectors of the cyclone type are usually located out-of-doors, on the roof or in some other place where a small amount of dust discharged from the stack will not be objectionable. A collector should not be located near open windows. If this cannot be avoided, the collector should be provided with a stack extending above the roof.

Cyclone collectors are usually applied at 3,000 to 3,200 inlet velocity, and under such conditions on grinding-wheel dust, the separation will usually be better than 95 per cent. However, a very small amount of extremely fine dust can create a considerable nuisance. Therefore, care must be exercised regarding the location of cyclone collectors.

The principal dimensions of cyclone collectors are shown by Fig. 22-7.

Where a high degree of separation is required or the cleaned air is to be recirculated, it is necessary to filter or scrub the air, as no centrifugal-type separator will remove fine dust to the degree required. If the dust loading is heavy, it is advisable to use a cyclone collector to remove the bulk of the dust and carry the exhaust from the stack of the cyclone to cloth-screen collector, scrubber, or other high-efficiency separator. Cloth-screen collectors are usually applied at around 3 ft of air per sq ft of cloth filter screen and under such conditions have an average resistance of 2 in. of water under normal operating conditions.

Hoods for the collection of coarse materials must be so shaped that the dispersed particles are thrown by the action of the cutter or wheel into the mouth of the hoods, since these large particles are thrown off with such a high velocity that their trajectories cannot be diverted by the inflowing air (see Fig. 22-8).

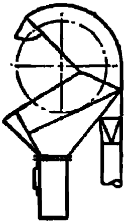

FIG. 22-8. Adjustable hood.

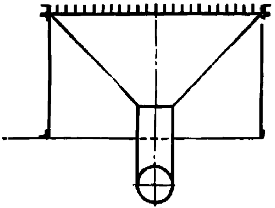

FIG. 22-9. Downdraft hood.

Dust produced by grinding and snagging operations on large and bulky castings may be controlled by downdraft hoods (Fig. 22-9) placed beneath the floor with a grating above them which serves as the work station. Air is drawn over the work down through the grating into the exhaust hood. Successful operation requires that the air velocity around the work be sufficient to remove the dust without objectionable drafts around the workmen's feet. A velocity of 200 fpm over the gross area of the grating will usually be sufficient. Where foundry shakeouts are handled by down draft, 250-ft velocity should be used for cold castings. If the castings are hot, it is necessary to overcome the tendency of the air and dust to rise, which will require around 400-ft velocity.

Foundry shakeouts, grinding, and similar operations may be conducted in booths having one end open and exhausting from the opposite end. The operations require from 100 to 200 fpm air velocity over the open end of the booth.

Processes such as belt and bucket conveyors, screws, etc., are controlled by the inward-leakage principle. The source of dust is enclosed as completely as practicable, and then sufficient air is exhausted from the enclosure to maintain an inward air leakage at all openings, cracks, and crevices. Where it is possible to compute the area of the openings, 150-ft velocity should be allowed over the total leakage area. In any case a liberal amount of exhaust air should be allowed.

Sand-blast rooms are provided with exhaust systems which remove the dust to facilitate the operations, but the dust level is still such that the operators are required to wear masks. Sand-blast rooms may be exhausted either by down draft or longitudinally. Usual air velocity is 70 fpm. Replacement-air inlets are required opposite the exhaust outlets.

Other than the definitely poisonous dusts such as lead, arsenic, mercury, etc., the most hazardous dusts to health are silica and asbestos. Control is usually by hoods and exhausted enclosures, with velocities ranging from 150 to 300 fpm.

Explosive Dusts. Practically all combustible materials when finely divided and suspended in air in the proper concentration can be ignited to produce a violent explosion. Dust explosions have occurred in plants handling coal, charcoal, grain, flour, feed, starch, sugar, powdered milk, wood dust, paper dust, cocoa, spices, hard-rubber dust, cork, sulfur, leather dust, and metal dusts. Of the metal dusts, magnesium and aluminum are particularly hazardous.

Where clouds of explosive dusts are given off, the hazard of a dust explosion can be much reduced by a well-designed dust-control system. However, unless suitable provisions are made in the design of such a system, it in itself may introduce an additional explosion hazard. Where explosive dusts are involved design should be in accordance with the detailed instructions given in "National Fire Codes for the Prevention of Dust Explosions."[1]*

FUME EXHAUST

In industrial plants and process industries, fumes, gases, vapors, and excessive heats are produced by machines, vats, tanks, furnaces, kettles, chemical processes, etc. Their presence represents an occupational health hazard as well as an obstruction to the efficient operation of the equipment. The fumes may be toxic or corrosive and require positive, complete, and continuous removal. On the other hand and according to the process, general and reasonable efficient removal may be all that is required. Between these extremes is a wide range of requirements, some relatively simple, others complex and difficult of accomplishment.

The usual methods of fume removal are general room exhaust, exhaust hoods at the points of contamination, and exhaust from booths and enclosures.

General exhaust is limited in its application (exhaust from hoods, booths, and enclosures is usually preferable) because it is necessary to remove such large quantities of air in order to reduce the percentage of contaminants in the room atmosphere to the proper level. Also, with general exhaust, there is a tendency for the air currents to short-circuit and fail to sweep out all areas. Where the fumes have a tendency to rise, as in foundries, exhaust through roof monitors is indicated, and where pickling and plating tanks are located along an outer wall, exhaust above the tanks and along the wall is quite effective. General exhaust should be so arranged that the natural movement of the fumes is towards the exhaust fans. This can be assisted by furnishing a positive replacement-air supply properly directed. Replacement air should enter the room at points where its velocity will assist the flow of fumes towards the exhaust fans. Cross drafts are to be particularly avoided. The secret of success of general exhaust is to handle large volumes of air, and for that reason direct exhaust without any or with very short ducts should be used. Under these conditions propellor or axial-flow fans, which handle large volumes of air at low pressures, are used. General exhaust requires an air change every 2 to 5 min, and in situations such as dye houses, heated replacement air must be supplied to absorb the moisture to prevent condensation and drip. Zoning the exhaust so that the greater portion of the exhausted air is taken from the most heavily contaminated areas is useful in keeping down the over-all amount of air removed from the building.

Side-wall exhaust above tanks requires a number of propellor fans spaced along the wall to obtain distribution. Satisfactory control requires the movement of around 750 cfm per lin ft of tank. Also, if the ceiling is high, a curtain or false ceiling about 8 ft above the tank is advisable so as to draw the air from the contaminated area. Open windows in the wall or other chances for air short circuit are to be avoided.

Fumes, smoke, vapor, and heated air which tends to rise from tanks, kettles, forges, furnaces, melting pots, and similar equipment are usually exhausted by means of canopy hoods (Figs. 22-10, 22-11, and 22-12). In addition to the usual funnel-shaped canopy hoods, there are double canopy hoods and those with side enclosures. The closer the hood is to the source of contaminant and the more completely the equipment is covered or enclosed, the better the results. The sides of the hoods should slope at an angle of approximately 45 deg with the vertical center line and should extend over the equipment by four-tenths the distance the hood is above the equipment. Air velocity over the face of canopy hoods ranges from 100 to 200 fpm. Duct velocities range from 2,000 to 3,000 fpm. With large hoods, connecting ducts should be branched so as to enter the hood at several points in order to obtain a uniform air flow over the face of the hood.

---

* Superior numbers indicate specific reference at the end of this section.

Double canopy hoods are arranged with an inside liner forming a narrow slot about ¾ in. wide around the rim. They also have a central opening under the connecting duct having about one-half the area of this duct. This central duct opening may be provided with a damper for adjustment. The theoretical advantage of canopy hoods is that the high velocity through the slot at the rim has a tendency to prevent smoke and fumes from curling outward at the edge of the hood.

Canopy hoods with side enclosures are useful where the operations will permit closing off the sides of the hoods and are quite essential where side drafts are involved. If enclosures cannot be permanent, movable curtains may be used.

Hoods over cooking ranges are usually placed with the back of the hood against a wall. The exhaust duct can be part of the hood and located as shown in Fig. 22-13. Exhaust openings should be provided with protecting baffles arranged to reduce the entrance of grease into the duct system. Ducts from range hoods should lead directly to outdoors, should be well separated from all walls and partitions, or insulated with heavy asbestos, since there is always a possibility of intense heat as accumulation of grease may take fire. Quite a common error is to exhaust range hoods into chimney flues. This seldom works out satisfactorily as the flue resistance is almost always too high for the amount of exhaust air required properly to remove the smoke.

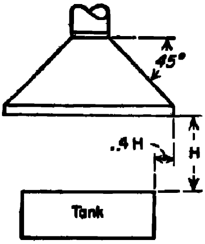

Fig. 22-10. Plain canopy hood.

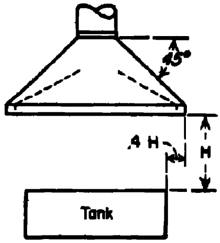

Fig. 22-11. Double canopy hood.

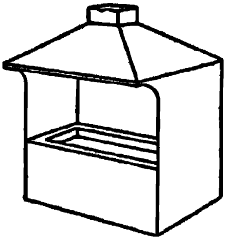

Fig. 22-12. Canopy hood with side enclosure.

Exhaust hoods should be placed as close to the source of the fumes as possible, without interfering with the process. Hoods should be arranged and shaped so that the fumes are directed by any natural air currents into the face of the hoods. Arrangement should be such that the operator is never between the source of the fumes and the hood. Cross drafts from open doors, windows, moving machinery, and heated objects may deflect the exhaust air currents requiring baffling or increased hood velocities. Convection air currents from furnaces and heated objects seldom exceed 75 fpm. Direct draft from open windows, doors, and moving machinery, however, may be of considerable magnitude.

Slotted hoods (Fig. 22-14) are used for exhausting from plating and pickling tanks where overhead cranes prevent the use of canopy hoods. The slots are usually 1¼ in. wide if flanged and 2 in. wide if not flanged. Air volume is based on a minimum of 150 cfm per sq ft of tank area. Slots should be located on three sides of the tank and, where tank is more than 3 ft wide, slot should extend along all four sides. Tanks over 5 ft wide are best handled by combined blow and exhaust hoods (Fig. 22-15). The pressure slot will range in width from ½ to 2 in. The exhaust air should be at least 200 cfm per sq ft of tank area. Air supplied by the pressure slot is one-quarter the exhaust air.

Downdraft exhaust is indicated when the vapors are heavier than normal air and there are no rising air currents to lift the vapors. However, if the vapors are hot,

Table 22-5. Average Air Velocities for Exhaust Hoods

Process	Type of hood	Average air velocity, fpm
Chemical laboratories	Enclosed hoods, sliding door	50–70 over gross opening
	Enclosed hoods, open front	70–90 over face of hood
	Downdraft table hoods	90–125 over fume-producing area of table
	Enclosed hoods in air-conditioned laboratories	Exhaust as above plus a supply of outside air equal to 90 per cent of exhaust air
Degreasing	Canopy hoods	125 over face of hood
	Slotted hoods for tanks up to 3 ft wide	1,500–2,000 through 2-in. slots
Disk grinding and sanding	Down draft through grating	200 over area of grating
Dry cans, padders, and slashers	Canopy and special hoods	25–35 cfm per sq ft of drying-cylinder surface, plus exhaust of 150 fpm over face area of mangle and size-box hoods
Electroplating	Canopy hoods for tanks up to 2 ft wide	125 over face of hood
	Canopy hoods for tanks over 2 ft wide	150 over face of hood
	Slotted hoods for tanks up to 2 ft wide	2,000 through 2-in. slots
	Slotted hoods for tanks over 2 ft wide	2,500 through 2-in. slots
Electric welding	Portable hoods	200 over face of hood
	Open-front booths	100 over face of booth
Foundry shakeout	Down-draft hoods	Hot castings 400 over hood Cold castings 250 over hood
	Open-front booths	150 over face of booth
Grain elevators	Bucket elevator boots	500 over face of hood
	Transfer points	400 over area of all openings
Granite cutting	Plain hood	Surfacing machine, rated on cfm, 540 cfm
	Flanged hood	Surfacing machine, 300 cfm
	Special portable hoods	Hand tools 200 at a point 6 in. from face of hood
Kitchen ranges	Canopy hoods	100–150 over face of hood, depending on size and use
Metal spraying	Open-front booths	Lead 200 over face of booth, zinc and other metals 125–150 over face of booth
Pickling metals	Canopy hoods	200 over face of hood
	Slotted hoods	200–250 cfm per sq ft of tank. Velocity = 2,000 fpm through slots
	Blow and exhaust	Exhaust 200–250 cfm per sq ft of tank. Velocity 2,000 fpm through slots. Blow 50–75 cfm per sq ft of tank. Velocity 3,000 to 5,000 fpm
Rubber mixing rolls	Canopy hoods	200 over face of hood
	Double hoods	2000 through 1½- to 2-in. slots
Steam kettles	Canopy hoods	150 over face of hood
Varnish kettles	Canopy hoods	200 over face of hood

NOTES: 1. Double hoods are usually applied at around 75 per cent of the face velocity of a corresponding canopy hood and with a velocity of 1,000 to 2,000 fpm through the slot at the periphery of the hood.

2. Canopy hoods with side enclosures are usually applied at 100- to 125-fpm velocity over operating area of hood.

3. Air that has been exhausted from a building must be replaced either by infiltration or, if of appreciable quantity, preferably by a fan supply system arranged with heaters to raise the outdoor air to room temperature.

even if heavier than air, the tendency will probably be for them to rise. Successful downdraft exhaust requires that the air velocity be sufficient to control the vapors but not so great as to create objectionable drafts around the workmen's feet.

Air velocities for exhaust hoods (see Table 22-5) vary with local conditions, the severity and toxicity of the fumes, the degree of hood enclosure, and the possibility of cross drafts.

Fan Requirements. *Air Volume.* The volume of air handled by an exhaust system is determined by the total effective connected load area and the suction at the hood connections. By load area is meant the area at the throat of the hoods. The hoods cause a restriction of the air flow which varies with the construction of the hoods and per cent of open area. Bell-mouthed hoods may have an effective area of 95 per cent of gross area, while a thin plate orifice will be around 60 per cent. While restrictive effect will vary from hood to hood, field tests have shown that 70 per cent of the total gross load area is a good average for the net effective load area of the usual exhaust system.

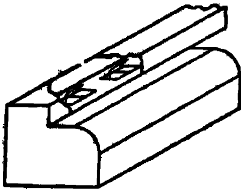

FIG. 22-13. Kitchen hood.

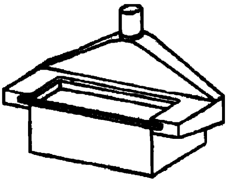

FIG. 22-14. Slotted hood

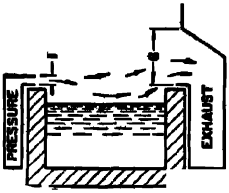

FIG. 22-15. Blow and exhaust hoods.

The velocity of air flow over this area is determined by the formula

$$V = 4{,}000\sqrt{i}$$

where V = air velocity, fpm

i = suction at the hood throat, in. of water

Cubic feet of air per minute (cfm) handled by the system is equal to total net effective load area (in square feet) times air velocity; or cfm = $0.70\,AV$, where A = gross load area in square feet, and V = air velocity in feet per minute

Air volume may also be determined by reference to Table 22-6. Individual volumes for each hood connection are taken from the table and added together to obtain the air volume which the fan must handle.

Table 22-6. Air Volume, Cfm, Handled through Average Collecting Hoods

(Cubic feet of air at 0.075 density handled per minute through average collecting hoods based on coefficient of entry of 0.71 with 10 per cent added for leakage)

Diameter of connection pipe, in.	Maintained suction-in. water gauge						
	1	1½	2	2½	3	4	5
	Vel. = 3,130	Vel. = 3,830	Vel. = 4,430	Vel. = 4,950	Vel. = 5,420	Vel. = 6,260	Vel. = 7,000
1½	38	47	54	61	67	76	86
2	68	84	97	108	118	136	153
2½	107	131	151	168	185	214	238
3	153	188	217	243	266	306	343
3½	209	256	296	330	362	418	466
4	273	334	386	431	473	546	609
4½	345	423	488	546	598	690	775
5	427	523	605	676	741	854	955
6	614	751	867	970	1,062	1,228	1,373
7	835	1,023	1,181	1,322	1,448	1,670	1,870
8	1,092	1,337	1,546	1,727	1,892	2,184	2,440
9	1,381	1,694	1,953	2,184	2,387	2,762	3,091
10	1,705	2,090	2,409	2,695	2,559	3,410	3,806

Exhaust from canopy hoods, slots, and similar applications is usually determined on the basis of a given air velocity over the particular opening. In applications of this type, it is usual to assume the effective orifice area as 70 per cent of the gross area.

Fan Pressure. As soon as air starts to flow in a duct system, a resistance to the flow is set up which must be overcome by the fan pressure in order for the air flow to continue. This resistance to flow is called maintained resistance, which is equivalent to the static pressure that must be produced by the fan.

The maintained resistance is composed of a number of factors, the most important ones being frictional losses in the ducts, losses caused by changes in velocity, work to get the air into the system and bring it up to the required velocity, and resistance of collectors and filters.

To determine the maintained resistance of a system, the point of maximum resistance either must be determined by inspection or trial. This may or may not be at the far end of the system, since a long branch of small diameter may have greater resistance than the additional main from junction point to its far end. Starting at the point of maximum resistance, the maintained resistance of the system is represented by the formula

$$R = W + P + K + E + N$$

where R = maintained resistance = fan static, in. of water
W = work required to get the air into the system and up to the required velocity
P = pipe friction
K = collector resistance
E = pressure drop due to changes in velocity
N = other losses if any

The work W required to get the air into the system will vary with the type of hood or opening into the duct and the suction or air velocity at this opening. Field experience and tests have shown that for average conditions W can be taken as one-half the suction at the hood. Or in the case of a velocity rating at the hood, W is taken as equivalent to the velocity head corresponding to the velocity in the suction pipe. Experience has shown that entrance coefficient on these systems will average close to 70 per cent, which is consistent with the method of determining work at hood entrance.

Pipe Friction. Experience has indicated that friction resistance figured as equivalent to one velocity head loss in 50 diameters of length of pipe will cover the normal loss with sufficient additional allowance to cover the effect of joints and unevenness of commercial pipe and flow of material in the air stream.

Expressed algebraically the pipe friction in straight round pipe, handling air at standard density is

$$P = (L/50) \times (12/d) \times i$$

where P = pipe friction, in. of water
L = length of pipe, ft
d = diameter of pipe, in.
i = velocity head = $(V/4{,}000)^2$
V = air velocity, fpm

For rectangular pipe the friction is increased by the ratio of the perimeter of the rectangular duct to the perimeter of a round duct of equivalent area.

Friction drop in elbows having a center-line radius equal to twice the pipe diameter is taken as equivalent to 8 diameters of length of pipe; for center-line radius equal to pipe diameter, 12 diameters of length.

Collector resistance for cyclone type of standard design, as shown in Fig. 22-7, is given by the formula

$$K = C(V/1{,}000)^2$$

where K = resistance, in. of water
V = entrance air velocity, fpm
C = constant—average value 0.2

Pressure Drop Due to Changes in Velocities. In abrupt enlargement of pipe and consequent drop in velocity, there is a pressure loss which can be taken as from one-half to the full difference in velocity heads corresponding to the initial and final velocities. The more abrupt the enlargement, the greater the percentage loss. If the enlargement is on a gradual taper, the loss is small and may be neglected.

Other Pressure Drops. Collectors of the cloth-bag or screen type run about 2 in. of water loss. Oil-type filters average $\frac{1}{10}$ to $\frac{3}{10}$ in. Paper-filter collectors run about the same as cloth-screen collectors.

CRUSHING AND GRINDING

BY HARLOWE HARDINGE

President, Hardinge Company, Inc.

AND E. B. DOELP

Engineer, Hardinge Company, Inc.

FUNDAMENTAL PRINCIPLES

The subject of crushing and grinding covers a field so broad and with so many applications that it is difficult to cover the fundamental principles in a way that will apply to the majority of cases found in industrial and metallurgical practices. Crushing and grinding of various materials is carried on usually for one of two reasons: either so that reduction is effected in order that values may be extracted from an ore, or the entire material being ground is a process material for commercial purposes, such as silica and feldspar in the pottery trade, powdered coal for firing of furnaces, limestone and cement in the cement trade, and for many other uses too great in number to enumerate here.

The dividing line between crushing and grinding is not sharp and will vary with different materials being reduced as well as the type of machine effecting the reduction. For this reason certain machines are built to do crushing only, others to do grinding only, and others will perform a combination of both. With but one or two exceptions, if the range of reduction is large, no one machine is capable of efficiently reducing the material through the entire crushing and grinding range. As many as five different crushing and grinding operations are required to reduce a 4- to 6-ft-diameter boulder down to a slime or fine powder, and the method of making this reduction will be shown later when discussing the various types of equipment used.

The materials to be crushed and ground will vary greatly in hardness, and it therefore stands to reason that the hard materials will be much more difficult to crush and grind than will the relatively soft materials. For this reason different types of machines should be used to suit different conditions. To grind and crush soft materials, the more complicated and less expensive type of pulverizer is usually used; but for hard materials, the crushing and grinding equipment must be of sturdy construction and simple design to withstand the severe usage and strains encountered in effecting the necessary reduction. In general, the ores encountered in metallurgical practice are considered comparatively hard as compared with many materials crushed and ground for industrial uses.

CRUSHING

Crushing is a mechanical operation which may be defined as a process of breaking down a material by impact or direct pressure sufficient to cause the material to fracture.

Crushing, as applied in present-day practice, is limited to the size of machine that can be used and to the cost of reduction by this method. Crushers are now available for large-scale operations that will handle rock as large as 8 ft diameter, but where tonnage is low and labor is relatively cheap, it may be economically feasible to install a smaller crusher with a receiving opening to take approximately 70 to 80 per cent of the feed, then sledging or blasting the very large pieces to a size small enough to feed to the crusher. To disintegrate economically materials by the simple crushing action, products are seldom finer than ½ in., though on rare occasions they may be reduced to 10 or 12 mesh.

Crushing machines must be very sturdy and capable of withstanding severe shock and strain, as reduction by crushing requires a great deal of force. Literally hundreds of types of crushers and rolls have been tried out in the past, but of these only a few have survived.

It is necessary to maintain a very definite relationship between the size of feed opening of the jaw crusher and the size of the bottom or discharge opening. This relationship is termed "ratio of reduction." The most efficient ratio of reduction consistent with economical operation is about four diameters, *i.e.*, when the maximum size of feed to the crusher is 4 ft, the most effective work can be accomplished if the discharge is approximately 1 ft. However, the loss in efficiency by increasing the ratio of reduction is often offset by the fact that fewer stages will be required to reduce further the larger pieces, and for this reason, most crushers are designed to effect a greater ratio of reduction than the ideal. In practice, ratios up to 8:1 are sometimes used.

Crushers are designed to operate on the principle of a huge nutcracker. The material to be crushed is dropped between two surfaces so inclined in respect to each other that the opening at the top is larger than the largest piece of material, and the opening at the bottom may be adjusted to the size of product desired. One of the surfaces is made to move a short distance forward, and the material being crushed, being incapable of distortion, is broken under the tremendous pressure. However, the total power to do the crushing is far less than might be supposed, as the distance the crushing surface moves is comparatively slight. For instance, to crush run-of-mine rock from 6 to 1 ft at a rate of 400 tons per hour, about 250 hp is required; but to reduce this same quantity from 1 ft to 2 in. requires nearly 800 hp, with comparative increases on down the line.

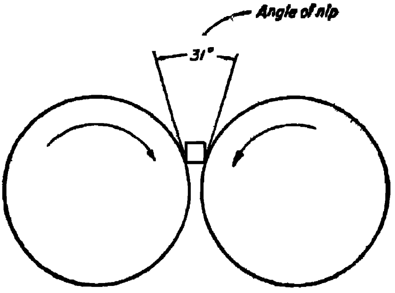

Fig. 23-1. Angle of nip.

Angle of Nip. In nearly all types of crushing devices, the crushing surfaces form an angle termed the "angle of nip." The angle between the crushing surfaces allows the pieces of material to be wedged and broken and then still further reduces the material by the wedging and breaking action as the smaller pieces of material progressively drop into the smaller space between the crusher jaws, until the material is finally discharged from the smallest opening between these jaws.

The angle of nip must be slight enough to prevent slippage of the material wedged between the crushing surfaces; but if the angle is too slight, the resulting ratio of reduction will be too small, and the crusher will not cover the necessary commercial range of reduction required.

The theoretical or critical angle of nip may be designated as that angle where the component of the forces that acts to hold the particles between the crushing surfaces by friction are just balanced by the components of the forces that tend to force the particle outward from the apex of the angle. The safe working angle of nip is therefore something less than the critical or theoretical angle. Theoretically, if there were no friction between the particle and the crushing surface, the only other force exerted would be by the weight of the particle to be wedged. The angle of nip would then have to be very slight to prevent slippage, which means that the safe angle of nip will be determined to a large extent by the friction of the particle against the crushing surfaces. The angle of nip will therefore vary widely depending upon the physical properties of the material being crushed, the character of the crushing surfaces employed, and the speed of approach.

When the crushing surfaces of the machines are round, *e.g.*, rolls, the angle of nip will vary at different points along the crushing surfaces. The angle of nip (Fig. 23-1) in this case is the angle formed by the intersection of two tangents drawn from the two points of contact of the material wedged between the crushing surfaces.

The angle of nip in jaw or gyratory crushers is nearly constant throughout the length of the crushing surfaces, and 31 deg is generally considered the safe working angle, although in an effort to make it possible to crush many different types of material with one machine, some manufacturers have adopted a lesser angle.

Rough rocks with sharp and abrasive characteristics or a rough or corrugated crushing surface will increase the frictional resistance between the crusher surface and the material, thus increasing the effective angle of nip.

Since the material fed to the crusher is not immediately accelerated to the speed of the crusher surfaces and may fail to be wedged between them, high speed of approach of the crushing surfaces will reduce the effective angle of nip.

The surface moisture characteristics of the material fed to the crusher also has some minor effect upon the angle of nip. Dry material is usually better than damp material since clay or fine particles adhering to the surface of damp material will tend to lower the coefficient of friction. However, the coefficient of friction is usually increased if the material sent to the crusher is very wet, owing to the washing away of the clay and fine particles and to the exposure of a clean surface.

TYPES OF CRUSHERS

The various types of crushing devices in practice are known as "primary breakers" and "reduction crushers." These may be either the moving-jaw type or the gyratory crusher. Where the range of reduction is large, these crushers may be operated in series; as many as three stages of so-called "primary breakers" in some cases may be used to advantage, the final product being 1 to ½ in. In general, gyratory crushers will have considerably more capacity when reducing to any given size than will jaw crushers of equal feed opening, and for this reason, when large pieces of material are to be fed, the jaw crusher is often used as the primary breaker. This selection is due to the fact that for a rated capacity the jaw crusher will provide a greater feed opening.

The reduction crusher may take feed as large as 4 to 6 in. and in one operation produce a product all passing ½ in. In practice, the types of reduction crushers generally used are the Dodge, reduction gyratory, rolls, and swing hammer. The latter two types are often used to effect a reduction down to 10 or 12 mesh and are sometimes used to produce an even finer product. This, however, is not generally recommended.

The advantages of adapting one or more of the various mechanical principles found in the crusher to pulverize material have been recognized. If certain of these mechanical advantages could be successfully applied, there would be a considerable saving in the amount of power required, and the character of the product could be more closely controlled than is now possible with the grinding devices currently in use. However, with the exception of some highly limited applications, no such device has been successful. Much difficulty has been experienced when attempts are made to effect fine reduction by the use of the several principles embodied in crushers. As the fineness is increased, the crushing surface must also be greatly increased. The crusher then becomes excessively wide at the point where the fine material is produced, and the movement of the crusher surface, even though small at this point, becomes exceedingly difficult to maintain mechanically. The crushing surfaces are subject to wear, and a very small amount of wear will cause a change in clearance, which in turn will have a major effect on the fineness of the product. In addition, serious complications will be presented by any moisture present in the material, which tends to cause the fines to agglomerate or pack, this being even more serious with reduction crushers when attempting to crush damp material close to their limiting size range.

Some of the grinding devices now in use (see page 1540) do utilize one or more of the basic crushing principles, but in an attempt to avoid the difficulties mentioned above, they will in most cases sacrifice many of the advantages and the simple mechanical construction of the so-called crusher.

Double-toggle Blake Crusher. Jaw crushers are the simplest and most commonly used type of crushing equipment and are used primarily as coarse breakers. Of the three main types of jaw crushers, the most common and successful is the double-toggle Blake-type crusher which is manufactured by many concerns in many modified forms and in many sizes. The largest will take rock up to 8 ft in diameter, and the smallest commercial size will take a feed of around 3 to 4 in. The ratio of reduction may be varied within practical limits to suit the capacity and size requirements of the installation.

The principle of operation is simple. As shown by Fig. 23-2, there is one stationary jaw and one movable jaw, set at an angle to each other, with the large opening at the top to receive the coarse feed. The movable jaw is hinged at the top and oscillated by a toggle near the bottom, and though the coarse material is squeezed less near the top than are the finer particles near the bottom of the jaws, there is still sufficient movement to cause fracture of the large pieces. The resulting pieces then drop down and are further reduced in size in the narrowing opening and finally through the opening between the jaws at the bottom.

The movable jaw is strongly hinged at the top and is actuated through the toggles by the pitman. The pitman is made to move up and down by an eccentric on the crusher drive shaft. At the lower end of the pitman are toggles which are so adjusted that, when the pitman moves up and down, the toggles will exert a horizontal pressure which is transmitted to the lower end of the movable jaw. As the crushing stroke is only half the total cycle, a large flywheel is used to aid the operation during the crushing stroke. The toggles are designed to be the weakest member of the crusher. In the event some tramp iron or hard nonfriable material accidentally gets between the jaws, one or both toggles will break, and no further damage to the crusher will be caused. The movable jaw is held against the toggles at all times by means of a spring which prevents the toggles from jarring loose and dropping out.

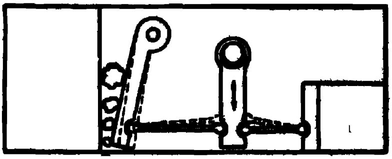

Fig. 23-2. Double-toggle Blake-type crusher.

The jaw plates are usually made of manganese steel to withstand the severe wear to which they are subjected, but several other alloy steels are also being used successfully. All wearing parts are constructed as simply as possible and are made easily replaceable.

To suit various conditions of the material being crushed, the size of the discharge opening, as well as the amount of swing of the movable jaw, may be adjusted. The end of the rear toggle is supported in a tail block, and the size of the discharge opening of the crusher may be adjusted by varying the thickness of shims between the tail block and the crusher frame. The length of stroke or movement of the crusher jaw may also be varied by adjustment of the tail block up or down by means of shims. The stroke is increased by raising the tail block which increases the angle of the rear toggle. Lowering the tail block by means of shims decreases the stroke. The swing of the jaw should be adjusted to suit both the nature of the material being crushed and the degree of fineness required. A long stroke is desirable for coarse crushing and maximum capacity, while a short stroke is more advantageous for fine crushing and to prevent the finer pieces from packing between the jaws.

Specifications of the Traylor-Blake-type double-toggle jaw crusher are given in Table 23-1.

Advantages. The outstanding advantage of the jaw crusher is that it has a larger feed opening, other conditions being equal, than do the gyratory or other types of crushers. For a rated capacity, a larger size of feed can be introduced into this crusher than into any other type. The required headroom for a jaw crusher is less than that of the gyratory crusher of equivalent size or capacity. The jaw plates can be readily inspected and are easily and quickly removed for replacement. The moving parts on the jaw crusher are more accessible for inspection and replacement than on the gyratory crusher. A variation in the length of stroke to suit the character and size of the crusher product can be readily obtained. The first cost of the jaw crusher is usually less than that of the gyratory crusher of equivalent size. The jaw crusher will operate on very hard, tough materials with a minimum of attention and can also handle many damp and sticky materials.

Disadvantages. As the jaw crusher performs useful work during only about one-half its operating cycle, *i.e.*, on the crushing stroke, the power required is usually somewhat greater than that required by an equivalent gyratory crusher. The jaw crusher will have a somewhat greater tendency to choke under heavy feed than will the gyratory crusher, this being caused partly by the large feed opening as compared with the capacity and partly because of the shape and motion of the crushing surfaces. The jaw crusher will not crush to so fine a size as will a gyratory crusher of equivalent capacity.

Table 23-1. Blake-type Double-toggle Jaw-crusher Data*

Size opening, in.	Approx shipping weight, lb	Max rpm driving pulley	Approx capacity per hr, tons of 2,000 lb				Size fly wheel, in.	Max hp required

* From Traylor Engineering and Manufacturing Company *Bulletin*

NOTE: Capacities are based upon materials weighing 100 lb per cu ft when crushed. Horsepower varies with the size of product, output, and hardness of material.

Dodge Crusher. The principle of operation of the Dodge jaw crusher is illustrated by Fig. 23-3. As with the Blake-type crusher, one plate is stationary and one movable, but the movable plate in the Dodge is hinged at the bottom rather than the top. Greater motion takes place at the feed opening than at the discharge opening. This type of construction prevents large pieces of material from dropping through the discharge opening on the backstroke, as occurs with the Blake; thus the Dodge crusher delivers a more uniform product.

Many features of the Dodge crusher are similar to those of the Blake crusher. Both of the crushing surfaces are covered with alloy-steel wearing plates which are quickly and easily removed for replacement. The movable jaw, which is hinged at the bottom on a large pin capable of withstanding very heavy strain, is moved by a strong lever which in turn is actuated by an eccentric on the main drive shaft. A heavy flywheel is used to reduce power consumption and balance the crushing operation. The adjustment of the opening is made by shimming backward or forward the packing blocks of the jaw shaft. Specifications covering the Dodge jaw crusher are given in Table 23-2.

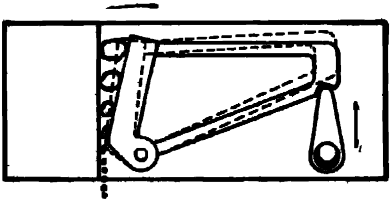

FIG. 23-3. Dodge crusher.

Advantages. The Dodge crusher is generally used as a reduction crusher, and it will produce a uniform product with a minimum of attention and adjustment. The angle of nip for a Dodge crusher is generally greater than that of the Blake type. The Dodge crusher is the simplest and least expensive of the standard-type crushers. This crusher is suitable for small-tonnage installations with a relatively high ratio of reduction.

Disadvantages. The Dodge crusher is less efficient than the Blake; it will choke if fed at too rapid a rate; and considering the floor space required and the power consumed, it does not have the capacity that several other types have.

Table 23-2. Dodge Crusher Data*

* From Allis-Chalmers Manufacturing Company *Bulletin*.

NOTE: Crushers may be operated in either direction. Capacities given are approximate and may vary either way according to the character of material to be broken and depend on distance the jaws are set apart and the speed. Hard stone or ore that breaks with a snap will go through faster than sandstone or similar material. Dodge crushers can be set up almost "tight" at discharge.

Single-toggle Jaw Crusher. The single-toggle jaw crusher, illustrated by Fig. 23-4, has one stationary jaw and a movable jaw operated by a mechanism which causes the jaw to be moved at the top as well as at the bottom. The movable jaw is hinged at the top and is mounted on an eccentric on the crusher drive shaft. The lower end of the movable jaw rests against a toggle, and the other end of the toggle is pivoted in a block on the stationary back frame of the crusher. Rotation of the eccentric shaft at the upper end of the movable jaw causes the jaw to move in and out and up and down. The discharge opening of the crusher may be regulated by placing shims or wedge blocks between the toggle block and the stationary back frame. In the event a finer product at lower capacity is desired, the in-and-out movement of the jaw at the bottom can be adjusted by raising or lowering the toggle block.

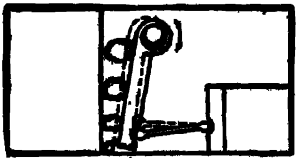

FIG. 23-4. Single-toggle crusher.

Operating data of Telsmith single-toggle jaw crushers are given in Table 23-3.

Advantages. The single-toggle jaw crusher will produce a more uniform product than the Blake type, and for the floor space required, the capacity is high. The construction is simple, and the moving and wearing parts are easily accessible. It is well suited for a moderate-sized installation. The ratio of reduction is good and will produce a good feed for fine-grinding equipment.

Disadvantages. Because the eccentric bearing must take all the weight of the jaw as well as the direct pressure caused by the crushing, there is high bearing pressure at this point. Owing to the heavy weight of the movable jaw, it has not proved practicable to build this type of crusher in large sizes. The rolling motion of the movable jaw plate, which causes some sliding action on the material being crushed, will generally result in a higher wear rate of the jaw plate than experienced in the Blake crusher.

Gyratory Crusher. The gyratory crusher, like the jaw crusher, is often used as a primary breaker and is a modification of the jaw-crushing principle to obtain greater capacity. This crusher is constructed in many sizes to meet many conditions, including large-scale operations. Gyratory crushers are sometimes operated in series, and the second stage and possibly the third stage may still be considered primary crushing if the final product is still in the nature of 1½ in. maximum size.

* From Smith Engineering Works *Bulletin*.

Note: Where no rating is specified in capacity table for any certain discharge opening, crusher cannot be operated economically at that opening. The capacities given are in tons of 2,000 lb and are based on limestone weighing loose about 2,600 lb per cu yd and having a specific gravity of 2.6. The horsepower varies with the size of the product, the capacity, and the hardness of the rock.

For close settings, all undersize material should be removed from the feed so as to eliminate packing and excessive wear on the jaw dies.

No crusher, when set to any given discharge opening, will produce a product all of which will pass a screen opening of the same dimensions as the given discharge opening. The amount of oversize will vary with the character of the rock.

The principle of operation of the gyratory crusher is illustrated by Fig. 23-5. The outer section is a truncated cone, known as the "concave," and is open at the top and bottom. A heavy vertical shaft or spindle carrying a conical crushing surface, known as the "mantle," is suspended in the center of the outer section and is hinged at the top. The lower end of the central shaft is gyrated in a path slightly off the center of the machine, which causes the surface of the mantle to approach the surface of the concave at different points during each revolution. The material to be crushed is dumped on top of the crusher and will lodge in all parts of the annular opening and will be crushed by the same pinching action as described for the jaw crusher. Owing to its circular action, every movement of the gyratory crusher is capable of crushing material, and it will discharge a product continuously; whereas the jaw crusher crushes only about one-half the time. As the crushing action and loading are more continuous than in the jaw-type crusher, the gyratory crusher does not require a heavy flywheel.

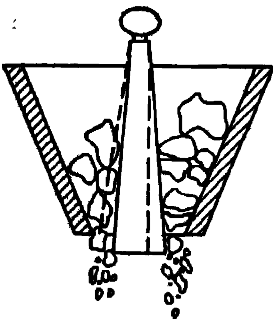

Fig. 23-5. Gyratory crusher.

The central shaft or spindle is rigidly supported and hinged on a swivel joint at the top. The crushing head is fastened to the central shaft and is constructed so that it may be readily replaced when worn. The shell liners on the outer stationary member of the crusher are also readily accessible for inspection and replacement. At the lower end of the central shaft is located the crusher driving mechanism, which consists of an eccentric on which is located a gear. This gear in turn is driven by a pinion fastened to the crusher drive shaft. As the eccentric rotates, it causes the lower end of the shaft to describe a small circle, while the upper end of the shaft is hinged at one point; and the gyrating movement of this shaft changes the distance once each revolution from maximum to minimum between the crushing head on the shaft and the adjacent point on the shell liners. The leverage thus secured by this principle is similar to the pinching action of the jaw crusher and is sufficient to produce a great crushing force. The product is discharged through the bottom annular space between the crushing head and the concave.

A shear pin is
to the drive shaft. This pin is designed to be the weakest member of the drive and will break first in the event any tramp iron or other substance impossible to fracture and too large to pass drops into the crusher. On smaller sizes of gyratory crushers used for intermediate and reduction crushers, the central head is sometimes supported hydraulically and is arranged to open momentarily to allow the passage of tramp iron or any other injurious materials.

Adjustment of the size of the discharge opening of the crusher is performed by raising or lowering the central shaft by means of an adjusting nut located at the top of the shaft. As the conical mantle or crushing head carried by the central shaft extends below the discharge opening of the concave, raising the central shaft will decrease the opening and decrease the size of product produced. Lowering the shaft will increase the opening and the size of the product.

Advantages. As the crushing action of the gyratory crusher is continuous and all motion is available for crushing, less power is required, and the capacity will be greater than the equivalent jaw crusher. It has a higher capacity in proportion to the floor space occupied. When operating, there is less vibration than with the jaw crusher. The gyratory crusher will handle a choke feed to better advantage than will the jaw crusher. It will reduce a slabby feed to better advantage.

Disadvantages. The gyratory crusher will require considerably more headroom than will the equivalent jaw crusher, and when all facts are considered, the gyratory crusher will usually have a higher first cost. The gyratory crusher will not take so large a size of feed as an equivalent-capacity jaw crusher, and wet or sticky materials tend to clog it. Data on Allis-Chalmers primary gyratory crushers are given in Table 23-4.

* From Allis-Chalmers Manufacturing Company *Bulletin*.

NOTE: Capacities tabulated above are estimated for average conditions and must be considered approximate. They are based on full continuous feed of quarry or mine-run material weighing 100 lb per cu ft, crushed. The size of crusher indicates the width of feed opening. For special conditions, minimum discharge opening may be decreased or maximum increased depending on characteristics of material to be crushed.

Reduction Gyratory Crusher. Reduction gyratory crushers, because of their high capacity, have reasonably large ratios of reduction. They have met wide use as secondary crushers and are sometimes used as tertiary crushers in very large operations. Where the initial feed to the crusher is relatively small, reduction gyratory crushers may in some instances be used as primary breakers. If the material undergoing reduction is friable and not sticky, this type of crusher may be adapted for crushing down to a size that begins to compete with rod or ball mills.

Reduction gyratory crushers are of basically high speed and are closely set as compared with the standard gyratory crushers.

Symons Cone Crusher. The Symons cone crusher is shown schematically by Fig. 23-6. It is in effect a gyratory reduction crusher but employs a modified principle of operation different from the standard gyratory crushers. The crushing head gyrates in much the same manner as the standard gyratory crusher, but it gyrates several times as far and at a much higher speed. This action of high speed and wide travel results in the material receiving a series of rapid hammerlike blows as it passes downward through the crushing chamber. The pieces of material being reduced pass through the crushing cavity in a series of bounces caused by the high speed of the crushing head, which, as it recedes from the closed position and from under the material, permits each piece of material to fall vertically a short distance before the crushing head comes up again for another crushing impact.

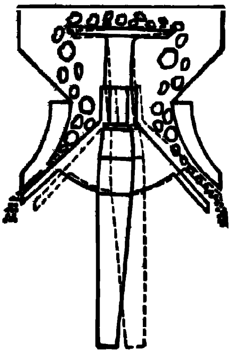

FIG. 23-6. Symons cone-crusher principle.

Because of the short time cycle consumed in one revolution of the crushing head, the material is subjected to a number of crushing impact blows before it can pass through the crushing chamber. As the material continues to move downward, it reaches the lower portion of the crushing chamber where the crushing surfaces are parallel for some distance. This parallel zone is of such length that the material in passing through will receive at least one impact from the crushing head, and all pieces discharged will have at least one dimension no larger than the minimum opening in the parallel zone. The width of opening at the parallel zone on the closed side will regulate the size of product discharged, rather than the open-side dimension as is the case with the gyratory crusher. Sizes, capacities, and power of Symons cone crushers are given in Table 23-5.

Symons cone crushers are protected against damage by a circle of heavy coil springs, which for normal operation hold the stationary crushing concave down firmly on the frame. When tramp iron enters the crushing cavity, these springs are compressed with each revolution of the head, allowing the concave to rise until the noncrushable material has passed into the discharge. These springs automatically return the concave to its normal position after the passage of the injurious material.

Advantages. The Symons cone crusher has much the same advantages as the gyratory crusher. It has a relatively large ratio of reduction, power consumption is economical, and it delivers a uniform size of product at high capacity per floor space required and power consumed. Maintenance is relatively low.

Disadvantages. The Symons cone crusher has a high first cost, particularly for relatively low capacity where the Dodge crusher can be used. It must be adjusted regularly to maintain a specified size of product, and it tends to choke with damp or sticky materials.

Rolls. Rolls, though a different principle from any of the types already described, may be classified as reduction crushers. They are primarily adapted for use where it is desired to crush a final product finer than the previously described types of reduction crushers can.

The ratio of reduction per roll should not exceed 4:1, and for this reason rolls are sometimes operated in series.

Generally, the size of feed is within the range of 3 to ½ in. In exceptional cases, rolls have been built to handle feed as coarse as 5 to 9 in., reducing this to a product of approximately 2 in. They can also be constructed to take a feed of as fine as ¼ in., discharging a product of 10 to 12 mesh, but this operation approaches that of the grinding mill. Only in exceptional cases are rolls recommended for fine reduction, as various types of grinding mills can accomplish the work to a much better advantage.

* From Nordberg Manufacturing Company *Bulletin*.

NOTE: The capacities given are neither minimum nor maximum but are a conservative estimate based on results secured in actual practice.

A diagrammatical view of a set of rolls is shown by Fig. 23-7. The principle of operation of rolls is that of two cylinders with axes and faces parallel and with adjacent faces revolving downward, so that when material is dropped between them it is broken by the pinching and crushing action produced. Either or both of the rolls may be positively driven. The capacity depends upon the size of feed, size of product desired, speed of the rolls, and width of roll face but will vary only slightly with the hardness of the material being crushed when operated under proper conditions. The bearings for one roll are fixed on the base, while the bearings for the other roll slide on the base and are backed by compression springs. This arrangement permits the rolls to move apart and pass any tramp iron or noncrushable material. After tramp iron has passed through the rolls, the compression springs will push the roll into its former operating position without interrupting the functioning of the machine. There should be no movement of the rolls or compression springs when the rolls are properly adjusted and crushing the material for which they were designed. The rolls are kept apart the proper distance by shims between the bearing bases. The shells of the rolls are made replaceable to provide for wear on the crushing surfaces. Bearings are made very heavy in order to withstand the high pressures which are exerted when the rolls are fed to capacity.

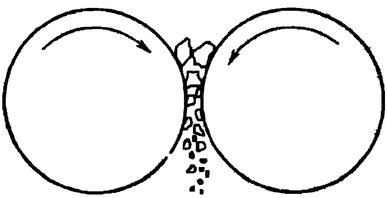

FIG. 23-7. Crushing rolls.

One of the main reasons why rolls cannot be used to better advantage for medium-fine crushing is that the surfaces of the rolls tends to corrugate, thus making it impossible to secure a uniform product when slightly worn. Various schemes have been employed in an attempt to correct this fault, and the method most generally used is to make one roll adjustable laterally. When corrugation starts, this roll is moved laterally slightly, thus placing different surfaces opposite one another and reducing the tendency to corrugate the surface. One type of roll provides for this lateral movement to take place continuously by means of a mechanically actuated end thrust bearing. Another method consists of placing a flat abrasive grinding stone against the ridges as they operate and wear them down. This method requires a great deal of attention, but it occasionally is the only alternative other than to remove the rolls and turn down or replace the faces.

Various specifications for Traylor crushing rolls are given in Table 23-6.

Table 23-6. Crushing-roll Data*

Size of roll diam by face, in.	Approx capacity, tons of 2,000 lb per hr			Rolls without automatic lateral adjusting mechanism		Rpm (usual range)	Hp required
	Size product, in.	Max feed, in.	Capacity, tons	Movable and fixed pulleys, in.	Approx shipping wt, lb		
18 × 10	⅛	⅝	5	24 × 8	5,600	250–300	8
24 × 12	⅛	⅞	10	48 × 6	11,800	180–230	10

* From Traylor Engineering and Manufacturing Company *Bulletin*.

NOTE: Capacities are based on materials weighing 100 lb per cu ft when crushed. The horsepower figures shown in the table are for medium capacities only and are based on a medium hardness of product. The actual horsepower required will depend entirely on the work to be done.

Advantages. Rolls are economical of power consumption and require less headroom and floor space than crushers of equivalent capacity. As long as the rolls have smooth surfaces, they will give a more uniform product than it is possible to obtain from any other type of crusher. They fill the gap between reduction crushing and grinding better than any other type of equipment.

Disadvantages. To keep them efficient, rolls require constant attention, and the repair cost is higher than on other crushing devices to do the same work. Corrugation greatly reduces the uniformity of the product as well as the capacity of the rolls. It is generally not economical to produce a product finer than 4 mesh with rolls.

Roll Data. The theoretical capacity of rolls can be obtained by computing the volume of the material passing between the rolls. In practice, the effective capacity of the rolls should be not more than one-quarter the theoretical capacity owing to the unequal character of the feed. The following formula is generally used:

$$DWS/(1{,}728 \times 4) = \text{effective capacity, cu ft/min}$$

where D = distance roll faces are separated, in.
W = width of face, in.
S = peripheral speed, in. per min

The capacity in weight is computed by multiplying the above capacity in cubic feet per minute by the weight per cubic foot of the material being crushed.

Roll Crusher. The roll crusher is a modification of the standard roll and is used for crushing relatively soft materials, such as bituminous coal, alum, salt, and similar materials.

The single-roll crusher consists of a toothed or corrugated roll revolving close to a very heavy stationary breaker plate which is curved and set closer to the roll at the bottom than at the top. The corrugations on the roll tend to increase the angle of nip or actually dig into the coarse lumps as they are fed through the opening above the roll, and in operation the material is crushed as it is dragged downward by the toothed roll and wedged into the decreasing space between the roll and the breaker plate. The material is discharged at a size not greater than the gap between the flat portion of the roll and the base of the stationary plate at the lower edge. The top edge of the

DRYING

BY R. J. RUSSELL

Chief of Technical Staff, Hardinge Company, Incorporated

INTRODUCTION

In general plant-engineering practice, drying is the removal of water from a solid by vaporization. Frequently drying is preceded by mechanical dewatering, filtering, or natural drainage to reduce the total cost of preparing a dry product.

Consideration must be given to the design and selection of drying equipment in order to meet the widely varying conditions encountered. In some instances drying must be carried out rapidly to preserve the properties and characteristics required of the dried material. Some materials must be dried slowly with careful control of temperature and humidity conditions to maintain uniform shrinkage. Other materials are not harmed or subject to deterioration during drying, but drying costs can be considerable, so proper drier selection is important.

DRYING FUNDAMENTALS

Vaporization of water proceeds as the vapor pressure exerted exceeds that of the surrounding atmosphere, and the process is accompanied by the absorption of heat. The heat supply is transferred by conduction, convection, or radiation separately or in combination.

Conduction is the flow of heat by direct contact from a heated body or surface to the material being dried.

Convection is the transfer of heat from heated air or gas to the material by passing over or through it.

Radiation is radiant energy in part absorbed by the material and transformed into heat.

Increasing the temperature of the water raises the vapor pressure and accelerates vaporization. The drying rate is proportional to the difference between the vapor pressure of the water and that of the surrounding atmosphere.

In some instances the water is held mechanically in pores or interstices in the solid. When this condition exists, the drying can proceed only as rapidly as the water proceeds by diffusion toward the surface of the solid.

The diffusion process also enters into surface evaporation. The solid is surrounded by a film of gas, and water vapor from the solid diffuses through this relatively stationary film. As the relative velocity of the gas to solid is increased, the film thickness is decreased, and surface evaporation is accelerated.

Air or other gas provides a medium for removal of water vapor from the drying chamber. Exceptions are when the vapor pressure exceeds atmospheric pressure and when drying occurs in a partial vacuum.

A definite and known vapor pressure exists for saturated water vapor at each temperature. When this vapor pressure exists in a given quantity of air at any specific temperature, the air is saturated. The slightest drop in temperature results in condensation of part of the water vapor. Conversely, any increase in temperature permits an increase in the amount of water vapor. Although many drying operations require a control of the ratio of water vapor to air or gas (humidity), rarely is the gas discharged from the drying system saturated (100 per cent humidity).

When the exhaust gases from a drying system are below the boiling point, there is a definite minimum quantity of air or gas necessary for removal of the water vapor. Where the source of heat for drying is the gases carrying away the water vapor, the quantity required generally exceeds the minimum limit. For indirect-heat drying, the minimum air requirement is of importance.

TYPES OF DRIERS

Drying may be a continuous or intermittent process. The intermittent or batch drier is simple in operation, and exact control of drying conditions can be maintained. Generally, thermal efficiency is low and labor requirements are high. Nevertheless, some materials can be dried successfully only in intermittent driers. The continuous drier is preferred and can be used satisfactorily in most instances.

Intermittent driers are known as chamber, compartment, or tray driers. Such driers consist of a chamber heated by steam coils with air circulated by natural convection currents or heated air induced through the chamber. The material may be supported on trays or otherwise suspended in the chamber. Some papers, leathers, ceramic ware, and lumber are best dried in such driers. In many instances drying must be carried out in accordance with a definite time schedule and with exacting temperature and humidity control.

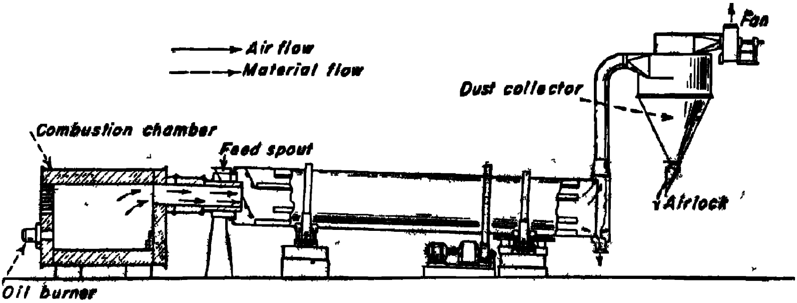

FIG. 24-1. Direct-heat parallel-flow drier. (*Hardinge Company, Inc.*)

Continuous driers are classified by the means for mechanically handling the material being dried. The following are the important types:

The *rotary drier* is a cylinder having internal baffles or flights to lift and lower the material being dried as the cylinder is rotated. Tires or riding rings are attached to the shell and supported on rollers or bearing wheels. One end is slightly elevated to accelerate passage of the material through the cylinder. A gear encircling the drier cylinder engages a driving pinion connected to a speed reducer and power source A fan or stack exhausts the drying gases.

Several types of rotary driers are available to meet a wide range of drying requirements. They are designated as direct-heat, indirect-heat, and reverse-current driers.

In the *direct-heat drier* the material being dried and the drying gases are in direct contact. The gases and material travel in the same direction in the parallel-flow drier (Fig. 24-1) and in opposite directions in the counterflow drier. A variation of the direct-heat drier passes the gases through the mass of material from louvers disposed around the periphery of the shell.

The *indirect-heat drier* is arranged to pass the heated gases through flues or ducts while the material is maintained in contact with the outer surfaces of the flues. Another arrangement has a bank of steam tubes suspended longitudinally within the shell and connected to a steam header as a heat source (Fig. 24-2).

The *reverse-current drier* consists of an inner flue supported within the drier cylinder through which the gases pass before reversing and flowing through annular space formed by the outer cylinder and the inner flue. Material travels through the annular space counter to the flow of gases (Fig. 24-3). An alternate design encases the drying cylinder in brickwork, passing the gases around the cylinder. They then flow through the cylinder counter to the travel of material. Another type has two or three concentric cylinders and transports the material in the gas stream through the smaller inner cylinder and then through the annular areas formed by the encircling larger cylinders.

Conveyor driers are of two principal types. Material is fed onto belts or screens which are mechanically driven to convey the material through a drying chamber, or electric vibrating conveyors may be used (Fig. 24-4). The heated gases pass over the material or through perforations in the conveying surface for the direct-heat types. Indirect drying is accomplished by heating the conveying deck on which the material is transported or by heat from a radiation source such as infrared lamps.

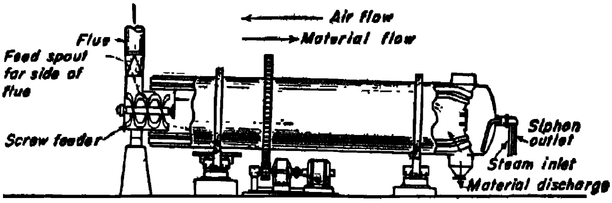

FIG. 24-2. Steam-tube drier. (*Hardinge Company, Inc.*)

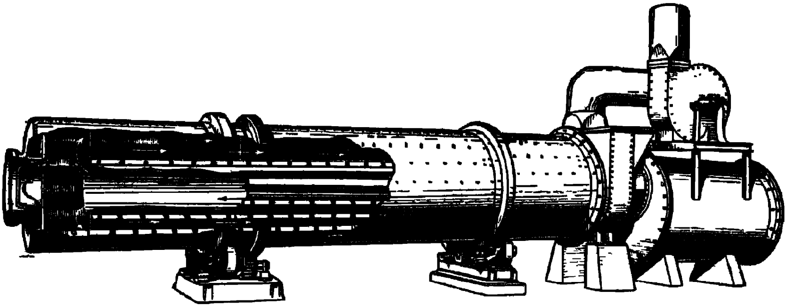

FIG. 24-3. Reverse-current drier. (*Hardinge Company, Inc.*)

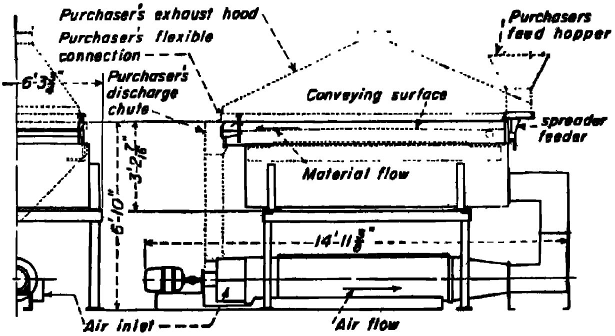

FIG. 24-4. Direct-heat conveyor drier. (*Jeffery Manufacturing Co.*)

Drum driers are used for fine materials usually in the form of a slurry before drying. The rotating drum is steam heated, and the material is fed to the drum from a weir at the top or by dipping the drum into the slurry. The thin film which adheres to the drum is scraped or brushed off after drying (Fig. 24-5). Speed is controlled to complete drying of the film in less than one complete revolution. Multiple drums or steam-heated rolls are used for drying paper, cloth, and similar materials.

Rapid vaporizing driers are known as flash, spray, and dispersion driers. Such driers are generally applicable for materials high in moisture and of very fine particle size. Drying is extremely rapid because of the large exposed surfaces of the material and the manner in which the material is brought into contact with the drying gases to produce a highly turbulent action (Fig. 24-6). The material is agitated by atomization from nozzles, dispersion from a rotating disk or wheel, or by introduction into a high-velocity gas stream.

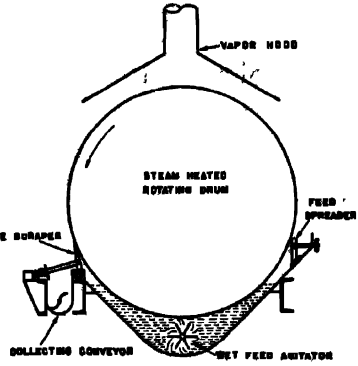

FIG. 24-5. Single-drum drier. (*Buffalo Foundry and Machine Co.*)

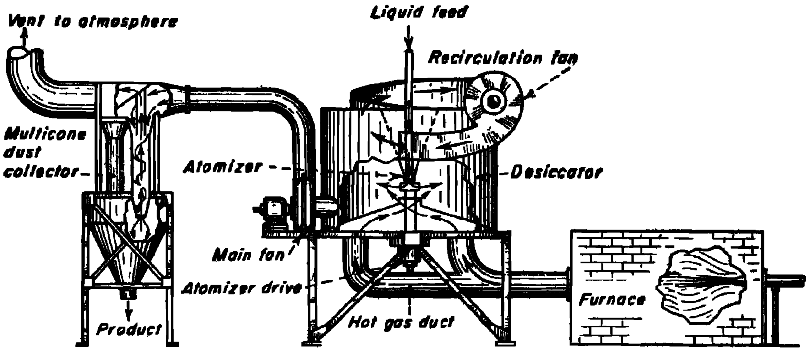

FIG. 24-6. Spray drier. (*Western Precipitation Co.*)

Vacuum drying may be used with special designs of spray, rotary, drum, and conveyor driers where the physical and chemical properties of the material require drying at low temperatures.

SELECTION OF DRYING EQUIPMENT

Every drying requirement is subject to certain limitations which in turn limit the types of driers which can be used. Although the drying capabilities of the several types are overlapping, no drier will handle each drying requirement equally well.

Certain physical and chemical properties of the dried material must be obtained or maintained to make it suitable for subsequent processing or marketing. These requirements are met by control in the drying operation of (1) final moisture content, (2) temperature, (3) drying time, (4) the means for handling the material, and (5) the drying medium.

The final moisture content is controlled by temperature, drying time, and controlled humidity of the drying medium. In rotary driers drying time is controlled by speed of rotation, slope of the shell, and the flight arrangement. The drying time of conveyor driers is also controlled by the rate of travel of the conveying mechanism.

Formed materials or materials destroyed by breakage must be dried by conveyor, tunnel, or batch driers. Rotary driers cause some breakage or reduction in particle size. Sheet materials such as paper require precise handling to allow for shrinkage in drying and yet maintain satisfactory strength qualities of the dry product.

Most driers can be adapted to use a suitable drying medium and can be equipped with automatic controls for temperature and humidity. Such controls often include as a part of the drying system recirculation of part of the gases and recycling part of the dried material.

HEAT REQUIREMENTS OF DRIERS

The theoretical heat requirements for a drying problem can be computed readily. Likewise, the minimum flow of gas required as a carrier for the water vapor can be determined. The basic laws governing flow of heat apply to all drying operations, but any attempt to apply them directly becomes quite involved. In commercial practice empirical formulas have been developed from the theory combined with experience factors.

Heat requirements for drying are

1. Heat required to raise the temperature of the water, vaporize, and in some instances superheat the vapor
2. Heat to raise the dry material to the discharge temperature above the entering temperature
3. Heat to the exhaust air or gases above the ambient temperature
4. Heat loss from the surfaces of the drying system to the surrounding atmosphere

The theoretical heat requirement for drying is that necessary to vaporize the water, or 970 to 1050 Btu per lb, depending upon the temperature at which vaporization occurs. In actual practice, driers require from 125 to 500 per cent of the theoretical heat with an average of 200 per cent.

Table 24-1. Drier Fuel Requirements and Capacities

Type of drier	Heat required, Btu/lb of water evaporated			Capacity factor		
	Temperature range of heat source			Temperature range		
	Low, 100–500°F	Intermediate, 500–1500°F	High, 1500–2500°F	Low, 100–500°F	Intermediate, 500–1500°F	High, 1500–2500°F
Rotary:						
Direct heat	2500–3500	2000–2500	1500–2000	0.3–1.0*	1.0–4.0	4.0–7.5
Indirect heat	3000–4500	2500–3000	2000–2500	0.2–1.0*	1.0–2.0	2.0–3.0
Indirect-direct	....	2000–2500	1500–2000	....	1.5–2.5*	2.5–4.0

Drum	1100–1500	....	....	2.0–6.0†		
Rapid vaporizing	3000–4500	2000–2500	....	0.2–1.0*	1.0–3.0	
Batch	3500–4500	2500–3500				

* Pounds of water evaporated per hour per cubic foot of drier volume.

† Pounds of water evaporated per hour per square foot of drying surface.

NOTES: Exit gas or air velocities for rotary range from 50 fpm for fine low-specific-gravity materials to 900 fpm for granular and coarse materials.

Conveyor driers maintain air velocity through or over the drying bed of 50 to 800 fpm.

Dust-collection equipment (dry cyclone collectors, wet collectors, or bag filters) must be used when complete recovery of dust is required.

Table 24-2. Performance and Cost Data of Ruggles-Coles Driers*

Type of rotary drier	Reverse current			Parallel flow, direct		Counterflow				Steam tube		Warm air
						Direct		Indirect				
Size, shell diam, in., by length, ft	70 × 35	70 × 35	90 × 55	104 × 80	90 × 55	60 × 40	90 × 75	60 × 35	90 × 55	48 × 30	70 × 30	48 × 25

Approximate factory cost†	15,000	15,000	30,000	40,000	26,000	10,000	26,000	15,000	36,000	8,000	12,000	5,000

* Hardinge Company, Incorporated.

† Factory cost covers driers, motors, and fuel-burning equipment.

Generally, when drying from a high initial moisture and delivering a product not entirely free of moisture, thermal requirements per unit of water evaporated are least. Drying to a low final moisture frequently is accompanied by a substantial heat loss as sensible heat in the dried product. A portion of this heat may be recovered economically from roasting or calcining operations, but rarely is it economically feasible in drying. Approximate heat requirements for drying are shown in Table 24-1.

DRIER DESIGN AND OPERATION

The factors that limit evaporating and drying capacity of a given drier are (1) the rate at which heat can be supplied or absorbed, (2) the conveying capacity of the drier, or the time required for drying, and (3) the velocity of the gases leaving the drier for direct-heat driers.

Laboratory tests are helpful in establishing a factor for drying time, and any changes in physical characteristics can be observed. Even though exact commercial drying conditions cannot be reproduced, data can be obtained which are useful in selecting a preferred type of drier and of value in approximating the size of drier for a specific drying requirement. A check is usually obtained by reference to known operations which are similar or comparable. Table 24-1 shows approximate design values for size determination.

DRYING COSTS

Fuel is the principal cost in thermal drying. From the heat requirements in Table 24-1 and a known or selected price for fuel, an approximate cost determination can be made. Power costs range from 10 to 20 per cent of the total drying cost. For other than batch or intermittent drying a single drier does not require the full-time attendance of an operator. Maintenance, lubrication, and incidentals rarely exceed 15 cents per ton of dry product and generally average about 5 cents. Equipment costs are as varied as the types of driers. The materials used in fabrication vary widely in costs, for where corrosive conditions occur, alloy metals are used. Table 24-2 gives data and approximate costs for several types of Ruggles-Coles rotary driers.

PERFORMANCE OF DRIERS

Frequently it is desirable to establish the performance of a drier installation. A batch drier test should complete four to six cycles, and the performance should be based upon an averaging of the results of each batch. For continuous driers the operation should be started and data recorded for test purposes after uniform conditions are reached. The test should then be carried out for not less than 8 hr and readings and samples taken at regular intervals.

Measurements to be taken and data recorded are

1. Amount of material entering and leaving drier
2. Per cent moisture content of wet and dry material
3. Quantity of heat (fuel, steam, or electrical heat supplied)
4. Power
5. Temperature and humidity of gases entering and leaving drier
6. Temperature of material entering and leaving drier

From the foregoing, performance results can be calculated and a heat balance determined. The difference between the heating value of the heat source and that totaled for raising the temperature, evaporating, and superheating the vapor of the water; sensible heat added to the product; and heat loss to exhaust gases is recorded as radiation, convection, and unaccounted-for losses. These losses range from 5 to 15 per cent of the total heat supplied.

INTRODUCTION

Information bearing on materials of construction, particularly those materials used in building corrosion-resistant chemical equipment, will be found in this section. The authors have screened and condensed available information into a brief form for the day-to-day use of plant engineers on practical materials problems. The material presented here, although brief, is authoritative, and while answers will be found to many practical corrosion problems, it is not the intention of the writers that corrosion testing be minimized. Rather the need for corrosion testing under controlled conditions is emphasized. Testing requires time but usually results in over-all economy.*

METHODS OF CORROSION TESTING

In the selection of a constructional material for service facilities and process equipment, all prospective candidates should be appraised on the basis of corrosion resistance and probable life, physical properties, prior performance in the same or similar applications, cost including fabrication and installation, availability in the shapes and forms required, applicable methods of fabrication and repair, anticipated maintenance costs, product contamination, desired life, and salvage value. The appraisal of materials of construction from the corrosion standpoint constitutes one of the most difficult phases of materials engineering. This is true particularly when a choice of materials must be made without benefit of service data and experience.

Materials of construction are either metallic or nonmetallic. The former class consists of metals and their alloys, and the latter includes such materials as glass, concrete, cement, refractories, rubber and rubberlike products, plastics, carbon, graphite, sulfur, silicon, wood, earthenware, stoneware, fused oxides, and many others. The methods employed in evaluating this large variety of materials, particularly in the laboratory or under artificial conditions, must be selected with great care. This applies in particular to the measures used in determining the degree of deterioration or attack.

The deterioration of metals and alloys sometimes takes the form of general attack in which the material is corroded more or less evenly over the exposed surface. Frequently metallic materials corrode by pitting. The corrosion in this case starts at selected areas, and the attack progresses inwardly from the surface. The total amount of metal affected is usually small even if failure is imminent. Corrosion of some metals also occurs through selective attack on certain constituents of the material. This type of corrosion is most frequently found in two-phase or polyphase alloys. It may be intergranular in nature, particularly when a secondary phase is present in or along the grain boundaries. Metals and alloys sometimes fail by stress cracking and stress-corrosion cracking. In failures of this type the actual quantity of metal affected by corrosion is often very small.

---

* In cases where more detailed information is required than is given in this section, the reader is referred to the sources listed in the bibliography at the end of this section.

In the nonmetallic group the various materials also deteriorate or are attacked in many ways. Rubber and rubberlike materials and plastics may embrittle, swell, or become tenderized. Bond failure sometimes occurs in rubber-lined equipment, while at the same time the sheet lining itself is affected negligibly. The resins used in making impervious graphite and carbon impose limitations in temperature and service conditions. Wood often fails by swelling or by reactions to form cellulose derivatives. The cement in transite reacts with certain acids leaving an asbestos skeleton. There may be a weight gain or a weight loss depending on whether the salts formed are soluble or insoluble in the corroding solution. This is also true in the reaction of refractories and concrete with acids.

The ideal corrosion-testing equipment would be designed to duplicate conditions to which the materials of construction are exposed under operating conditions. Such equipment would incorporate features making it possible to determine the effect of temperature, velocity, aeration, turbulence, entrainment, impingement, galvanic couples, plastic deformation, residual and applied stresses, and joining and fabrication methods on the corrosion rate. The cost of such equipment would approximate if not exceed that of a small-sized plant. Less costly methods are consequently employed. Those commonly used in the laboratory are the total-immersion test, the alternate-immersion test, the partial-immersion test, and the salt-spray test, the last being employed extensively for protective coatings.

The total-immersion test is the most widely used method. Test data obtained by this method are very valuable, although it is desirable to confirm results by special tests and by semiworks or plant exposure if this is possible.

Total-immersion Tests. *General Description.* The method of total-immersion tests consists essentially of immersing prepared and weighed samples in the test solution for a number of periods of usually two or more days' duration and determining the weight loss by cleaning and reweighing the samples after each period. The corrosion rate of metals and alloys is expressed as weight loss per unit area or as a penetration-rate factor, whichever is desired. If pitting, intergranular or other selective corrosion, or stress-corrosion cracking occurs, it is necessary to modify the method of reporting test data.

Equipment Required. Metal-cutting saws and disks and belt-polishing equipment are required to prepare the samples. If boiling tests are to be made, the testing equipment is generally constructed of glassware consisting of flasks equipped with water-cooled condensers. If the tests are made below the boiling temperature, air condensers or cover glasses may be sufficient to prevent loss of vapor during the test. Electrically or gas-heated hot plates or other suitable heating equipment are required for the boiling tests Constant-temperature baths or furnaces are suitable as heat sources for tests made below the boiling temperature. Glass cradles are generally used for supporting the samples in the test flask or beaker. Micrometers or calipers and an analytical balance are needed to determine the surface area and the weight and density of the samples. In some cases glass testing equipment is not suitable. Testing apparatus is then constructed of hard rubber, plastics, or suitable metals. Protective coatings are sometimes used on glass or metals depending on test conditions. It is also desirable, and in some cases necessary, to have a binocular and a metallurgical microscope and fine polishing equipment.

Size and Finish of Samples. The size and shape of samples should be in harmony with the testing equipment used. Samples that can be polished and measured quickly are preferred. For most purposes metal samples are finished on a 120-grit belt.

Volume of Test Solution. The quantity of test solution used should fulfill the following conditions. It should be sufficiently large that the decrease in the concentration of the active constituent or constituents is not appreciable during the test period. It should be sufficiently large that the accumulation of corrosive products during the test period is small. The volume of solution should be not less than 250 cc for a sample having a surface area of 30 sq cm. A volume of 1,000 to 1,500 cc is preferred for a sample of this size. Flasks of 1,000 cc capacity containing 600 to 700 cc of test solution and samples having a surface area of 10 to 20 sq cm make a satisfactory combination for boiling tests.

Temperature of Corroding Solution. Total-immersion tests may be run over a wide range of selected temperatures. The temperature of tests made below the boiling point should be controlled thermostatically to plus or minus 1°C. Fluctuation in barometric pressure will cause variation in the temperature of boiling tests. Such variations are normally disregarded.

Starting the Test. Metal samples are prepared and finished on a 120-grit belt or paper. They are washed and degreased if necessary, dried, measured, and weighed and the density determined if this is not known. The samples are placed in the cradles. They may be either immersed in the test solution before or after the testing temperature is reached. In boiling tests the samples are often placed in the flasks before the hot plates are turned on. Samples of dissimilar materials should not be placed in a common flask. It is permissible to test duplicates of the same material in a common flask, but the individual samples should not be in contact.

Duration of Test. Tests are generally run for at least 240 hr. This interval should consist of three to five periods of approximately 48 hr each. Fresh test solution should be used for each period. The time count should be started when the solution has reached the test temperature.

Cleaning Samples after Test. At the completion of a period the samples are removed from the test solution and cleaned. Cleaning in many cases can be accomplished by rubbing the samples with a rubber stopper or by brushing with a fiber bristle brush. The dislodged corrosion products are washed away with water. In certain cases the above treatment is not satisfactory.

In some such cases electrolytic cleaning is used, the sample being made the cathode of a cell. Inhibited 5 per cent sulfuric acid makes a suitable electrolyte for general use. Blanks should be run to determine metal weight loss in the cleaning operation, if any. In very troublesome cases either scraping or polishing may be required to clean the samples. The clean samples are finally degreased, if necessary, dried, and reweighed.

Calculation of Corrosion Rate. The corrosion of the samples may be expressed in a variety of ways. One common method employs the so-called "mdd rate" (milligrams per square decimeter per day). Another employs the ipy rate (inches penetration per year) or ipm (inches penetration per month). Some engineers prefer mils per month or mils per year instead of inches per month or inches per year. The calculation of the rate, inches penetration per month, is made as follows:

$$R = (283 \times W)/(A \times D \times t)$$

where R = corrosion rate, in. penetration per month
W = weight loss, grams
A = area, sq cm
D = density, grams/cc
t = time, hr

If pitting or intergranular corrosion or cracking has occurred, the above methods of reporting corrosion data have serious limitations. In the case of pitting, information on size and the number of pits per unit area and the maximum and average depth should be included. If intergranular corrosion occurs, it is often necessary to determine the penetration by microscopic methods. This can be done by fine polishing and examining a section cut from a corrosion coupon. This procedure may also be required if cracking has occurred.

Other methods are also employed in determining degree of deterioration during the test. The loss in tensile strength during test is sometimes used and is an excellent method if the material for tests can be obtained in suitable form for preparing tensile specimens. The decrease in electrical conductivity has been used for measuring intergranular corrosion of austenitic stainless steels.

When testing nonmetallics by the total-immersion tests, the changes in hardness, tensile strength, elongation, and dimensions are of more value than the weight loss or gain.

Special Total-immersion Testing. The effect of oxygen or other gases on the corrosion rate can be determined by introducing the desired gas into the test solution through a diffuser of porous glass or alundum, which is connected to an outside supply source. The supply line is introduced through the condenser tube or through corks or stoppers, if these are used. Oxygen has a marked effect on the corrosion of many metals. This should always be taken into consideration in making tests. The corrosion cracking of metals can be determined semiquantitatively by using U-bend specimens constrained with through bolts. Corrosion creep tests have been made on lead and lead alloys and some of the light metal alloys. Erosion corrosion tests are made to determine the effect of velocity and impingement on the rate of corrosion. It is also possible to obtain data on the corrosion of dissimilar metals in contact with the total-immersion-test method. Two total-immersion tests have been widely adopted for testing the stainless steels—the nitric acid test (ASTM A-262-44T) and the acid copper sulfate test (Strauss and modified Strauss).

Alternate-immersion Test. In this testing procedure special mechanical equipment is required which permits automatic immersion in and withdrawals of the samples from the test solution. The test is designed to determine the effect of alternate exposure to the corrodant and to air, such as occurs in many tanks, pipe lines, and on roofs. The tests are normally conducted at room temperature or only slightly above. The test period is usually longer than is employed in total-immersion testing. The procedure for preparing test samples and determining the degree of deterioration is the same as that used in the total-immersion test.

Partial-immersion Tests. In this test the samples are only partially immersed in the test liquid. The object of this test is to determine the rate of corrosion at the liquid-vapor level. This is important in constant-level tanks and in partially filled pipe lines.

Salt-spray Test (ASTM B-117-44T). This test is widely used for determining the corrosion resistance of protective coatings. It is also employed for testing light metal alloys and stainless steels. It finds its greatest use in selecting materials of construction for exposure to industrial and marine atmospheres and as a control for acceptance tests for certain finishes.

Precautions in Corrosion Testing. In addition to close control of temperature and of the composition of the corrodant, it is necessary to give careful attention to the composition of the material being tested. A small quantity of copper oxide in copper used at high temperatures under reducing conditions will cause rapid failure. The quantity of silicon normally present in semikilled and killed steels causes a rapid increase in the rate of corrosion by fluorine between 200 and 400°C. Lead in zinc-base zinc–aluminum alloys needs to be very carefully controlled to prevent corrosion. Many other examples are known.

A corrosion engineer should remember that to be useful a material of construction must be fabricated into the required shapes. Fabrication often requires hot or cold forming and joining parts by riveting, welding, soldering, brazing, bolting, cementing, and expanding or shrinking. The method of fabrication often determines to a considerable degree how the equipment performs corrosionwise once it is in service. In making corrosion tests these matters must be taken into consideration. The weld-decay corrosion of certain grades of stainless steel is an excellent example of how fabrication procedure may destroy the corrosion resistance of the material of construction. Crevice corrosion and the caustic embrittlement around rivet holes illustrate further what may happen as a result of the fabrication method.

Plant and Field Testing. Much corrosion testing is done in operating plants. In general, the same principle applies here as in the laboratory tests. It is often permissible to test simultaneously a variety of metals, particularly if the tests are made where recycling is not involved. Often the chief difficulty is in designing and building a suitable test rack. In making such racks it must be remembered that the samples must be insulated from the rack and from each other. ASTM A-224-41 outlines recommended practice for conducting plant tests.

SPECIFIC PROPERTIES OF SOME OF THE MORE COMMON METALS AND ALLOYS

Although upwards of four thousand metals and alloys have been listed by name, it may be said that the usual engineering functions of plant design, construction, and operation are concerned with a relatively small number of those listed. The authors have brought together useful information as regards physical properties and corrosion resistance on about sixty of the more commonly used metals and alloys, seventeen of which are classed as stainless alloys.

Brass. Brasses are alloys of copper and zinc containing up to 45 per cent zinc, usually produced in the wrought form in many compositions and in strengths ranging from 35,000 to 125,000 psi. The great variety of compositions, colors, and physical properties make the brasses one of the most useful classes of industrial alloys. *Gilding metal* (95 per cent copper, 5 per cent zinc) is gold-colored and used for jewelry and decorative purposes. *Red brass* (85 per cent copper, 15 per cent zinc), *low brass* (80 per cent copper, 20 per cent zinc), *cartridge brass* (70 per cent copper, 30 per cent zinc), *high brass* (66 per cent copper, 34 per cent zinc), and *Muntz metal* (60 per cent copper, 40 per cent zinc) are the more common varieties used for screws, rivets, condenser tubes, flexible hose, eyelets, springs, musical instruments, drawn shapes, valve stems, etc. Brasses are resistant to atmospheric corrosion but, in general, have slightly less corrosion resistance than pure copper or the copper–tin alloys. The higher the zinc content, the poorer the corrosion resistance to the more severe exposures. Brass suffers two types of corrosion which must be guarded against. *Dezincification* may occur when brasses are exposed to sea water or acidic river water under certain conditions. This peculiar corrosion is caused by dissolving of the brass and redeposition of the copper, resulting in a net loss of zinc. Dezincified areas then consist of a spongy copper deposit, which eventually penetrates the metal. *Season cracking*, often described as stress-corrosion cracking, causes cold-worked or externally stressed brass to crack spontaneously when exposed to moist ammonia atmospheres or mercury salt solutions. Annealing after cold forming will prevent season cracking.

Brasses, like copper, will work-harden after cold-forming operations. The tendency to work-harden increases as the zinc content increases. Hence, articles to be severely cold-worked should preferably be made of one of the low-zinc alloys in order to avoid unnecessary interstage annealing treatment. Brasses are usually tough machining materials, although the machinability increases as the zinc content increases. Free-machining brasses containing a small amount of lead are available and are known as "leaded brass."

Bronze (Tin Bronze). The term "bronze" generally refers to alloys of copper and tin, sometimes containing zinc or lead, which should be distinguished from other alloys such as aluminum bronze (copper–aluminum) and silicon bronze (copper–silicon). Bronzes are reasonably strong (tensile strength 30,000 psi) alloys generally used as castings. *Coinage bronze* contains 92 to 96 per cent copper, with the remainder tin to increase hardness and wearing qualities. *Government bronze*, composed of 88 per cent copper, 10 per cent tin, and 2 per cent zinc, is used for large castings. The addition of zinc increases the fluidity of the metal, producing more dense castings. Another composition is known as "85 and 3 fives" containing 85 per cent copper and 5 per cent each of tin, zinc, and lead, in which the lead is distributed throughout the metal, thus improving machinability. *Bearing bronzes* may be a phosphor bronze, in which phosphorus up to 1 per cent is added as a nonabrasive hardening agent, or a leaded bronze containing from 10 to 30 per cent lead uniformly distributed as small drops throughout the metal. Leaded bronzes are often used for severe bearing services, such as in locomotive journals. In general, the corrosion resistance of bronze is similar to that of copper. Bronze is used in the chemical and food industries for making cast articles to be used in mildly corrosive conditions, *e.g.*, as agitators or paddles in copper equipment. Strongly oxidizing conditions, such as nitric acid, are to be avoided. Bronze fittings are very resistant to atmospheric corrosion and find wide use in domestic and marine hardware.

Cast Iron. Gray cast iron, one of the most useful commonly used metals, is termed "gray" because of the typical color of a newly fractured surface. Gray cast iron is cheap, readily cast to shape, and easily machined. It is a brittle material but if carefully made may have a tensile strength of 60,000 psi with little or no elongation. Ordinary material has a tensile strength of 30,000 psi. Two valuable properties are good damping capacity and freedom from galling and seizing under friction. Gray cast-iron articles varying from a fraction of a pound to several tons are used as automotive cylinders and pistons, machine-tool castings, car wheels, flywheels, water pipe, and hardware.

By small changes in composition or by chilling during casting, *white cast iron* is produced. White cast iron is extremely hard and brittle and valuable for combating certain types of abrasive wear such as is found in plowshares, rolls, car wheels, dies, and wearing plates of various sorts.

Alloy Cast Iron. Nickel, chromium, and molybdenum are sometimes added as alloying elements. Nickel is added up to 5 per cent to improve machinability and to obtain improved combinations of strength, hardness, freedom from porosity, and wear resistance. The addition of 10 to 18 per cent nickel produces a nonmagnetic alloy having high corrosion and scale resistance.

Chromium is added to increase the tendency to chill or to form white iron. Up to 3 per cent chromium is used to produce additional hardness and wear resistance. Nickel-chromium cast iron is produced with various combinations of alloying elements to suit specific requirements.

Molybdenum, added in quantities from 0.25 to 1.25 per cent, increases the tensile strength, transverse strength, and hardness.

Cast irons may be welded successfully by the oxyacetylene or electric-arc processes, if preheated to avoid local hardening and cracking. Other joining methods are conventional brazing and silver brazing.

Malleable Iron. Malleable iron is a ductile form of cast iron, produced by extended annealing of a white cast iron. A tensile strength of 55,000 psi with an elongation of about 20 per cent (compared to elongation of 1 per cent less for gray cast iron) can be obtained. Malleable iron is used for castings that must withstand shock, such as in automobile parts, railway equipment, and agricultural machinery.

Copper. Copper is a strong, ductile, malleable metal which is reddish in color and which, with tin, zinc, nickel, silver, and many other metals, forms numerous commercial alloys of wide industrial application. Many of the alloys of copper possess physical properties such as tensile strength, elastic limit, reduction of area, and elongation that are a marked improvement for commercial purposes over pure copper. In the absence of oxygen, copper is quite resistant to dilute acetic acid. Copper is widely used in electrical equipment where high electrical conductivity is required. Of all the metals, copper is exceeded only by silver as an electrical conductor. Copper can be welded by electric arc, Heliarc arc, or by the oxyacetylene process. A deoxidized copper rod containing some residual phosphorus or boron is preferred. Copper may be brazed or silver brazed. If a joint of high strength is not required, the contact surfaces may be joined by soldering after first "tinning" the surfaces.

Ingot Iron. Ingot iron is a commercially pure grade of basic open-hearth iron, at least 99.8 per cent iron, with the carbon content at approximately 0.012 per cent. The tensile strength is 45,000 psi with an elongation of 45 per cent. Ingot iron is principally rolled into sheets and used for construction work where a ductile, comparatively rust-resistant metal is required. A large amount of ingot iron is sold as galvanized sheets. When alloyed with 0.4 per cent copper and 0.05 per cent molybdenum, ingot iron becomes *Toncan iron* and is claimed to have superior rust-resisting properties.

Silicon Iron. Silicon iron containing approximately 14.5 per cent silicon is available as Duriron or Corrosiron and is widely used as a cast alloy for the manufacture of corrosion-resistant pumps, valves, piping, and other equipment. The alloy can only be cast and is so hard as to be practically unmachinable. Finishing operations are usually done by grinding. The alloys are extremely brittle and cannot be handled roughly or subjected to severe thermal shock. However, in spite of these apparent disadvantages, when properly fabricated, silicon irons are unexcelled for the economical handling of hot nitric, sulfuric, and, to a lesser extent, hydrochloric acid. Silicon irons should not be used with alkali or hydrofluoric acid.

Lead. Lead is a soft, malleable, heavy metal (specific gravity 11.38) of relatively low tensile strength (3,000 psi), but it is widely used because of its resistance to corrosion by sulfuric acids and sulfates. It is readily fabricated by "lead burning" into various shapes for use in chemical equipment. Oxyhydrogen flame is the preferred means of heating. Lead is widely used as pipe and cable coverings, for process equipment handling sulfuric acid and sulfates, and in a variety of bearing alloys and related applications. One of the lesser known uses for lead is in "leaded" brass. During cooling and rolling of brass containing, say, up to 2 per cent of lead, the soft metal separates out, and the globules of lead are distributed throughout the body of the brass serving as a lubricant to the cutting tool and are the basis for "free-machining brass."

Monel. Monel metal is the trade name of a nickel-copper alloy obtained by smelting a natural ore of such a composition that an alloy of about 67 per cent copper, 28 per cent nickel is produced. Monel is a silvery white metal which may be cast, rolled, or forged. The tensile strength is 80,000 psi for annealed material and 140,000 psi for cold-drawn material. A free-machining grade (R-monel) having slightly increased sulfur content, is commercially available.

Monel is widely used in the food and chemical industries for its corrosion resistance both to atmospheric conditions and the more severe services such as dilute sulfuric acid, hydrofluoric acid, and alkali. Monel sheet is used in domestic kitchen furnishing and in architectural decorative work.

Monel is easily fabricated by drawing, stamping, rolling, and forging, although the material work hardens fairly rapidly. As with nickel, machining is best done with sharp high-speed or carbide tools, and care must be taken to avoid sulfurous atmospheres during annealing. Monel may be joined by fusion welding, using the oxyacetylene or electric-arc processes, or by resistance spot welding. Phosphorus-containing silver brazing alloys are to be avoided, but other silver brazing alloys flowing below 1400°F may be used. Soft solders are acceptable in certain services.

Nickel. Nickel is widely used in the commercially pure condition as wrought plate, bar, sheet, tube, and wire, and as shot for alloying purposes. Nickel is a silvery white metal having a tensile strength of about 70,000 psi which can be increased to 115,000 psi by cold working. Nickel is a tough metal, having high impact strength which is retained even at subzero temperatures. Nickel and nickel alloys constitute a large fraction of the "stainless" or rust-resisting metals.

Pure nickel is widely used for its corrosion resistance. It is generally resistant to nonoxidizing acid, neutral, and alkaline solutions; it is suitable for handling food products and may be used either as solid metal, clad plate, or electroplate. Nickel is extremely resistant to caustic solutions and nonoxidizing salt solutions but is readily attacked by sulfur at elevated temperatures.

Fabricating nickel requires special precautions in machining and annealing. Because nickel is strong and tough, high-speed steel or cemented carbide tools in good cutting conditions are required. The work should be well flooded with cutting lubricant and cut at moderate speeds and feeds. Annealing should be done in a sulfur-free atmosphere. Sulfur-bearing fuels or traces of sulfurized cutting oils on the work will cause severe attack on nickel during annealing. Nickel may be fusion welded by oxyacetylene or electric-arc methods or joined by silver brazing alloys (except phosphorous-bearing alloys) or soft soldering.

Silver. Pure silver has the whitest color and the highest electrical and thermal conductivity of all the metals. Pure silver (fine silver) is too soft for many mechanical uses. Hence it is usually alloyed with copper to increase physical strength and hardness. Sterling silver contains 7.5 per cent copper; coin silver, 10 per cent copper. Silver is used in the electrical industry for heavy bus bars and heavy-duty contact and also in the chemical industry because of its resistance to attack by acetic acid, brewery liquid, formaldehyde, phenol, and dilute sulfuric acid. The use of both cast and wrought silver in jewelry is well known. Silver is commercially available in sheet, plate, rod, tubing, and as clad plate, combined with base metals such as copper, nickel, or steel. Fabricated shapes are made by the fusion welding, using atomic-hydrogen torch or Heliarc process. Molten silver readily absorbs oxygen, creating "gassy" welds if improperly made. Annealing at 480°F will soften silver.

Silver Solder. Silver solders or, more properly, silver brazing alloys are perhaps the most convenient materials available for making reasonably high-strength joints between most of the common metals and alloys. Silver brazing alloys include a wide range of compositions containing from 5 to 80 per cent silver, combined with varying amounts of copper, zinc, cadmium, or phosphorus. One of the principal advantages of silver brazing alloys is the free-flowing nature of the melted alloy. Actually, the strongest joints are made with very small clearances. Silver brazing alloys possess about the same corrosion resistance as brass, copper, nickel silver, and monel. The procedure for using silver brazing alloys consists essentially of (1) removing all scale, grease, and dirt; (2) applying the proper brazing flux; (3) maintaining desired alignment of the pieces to be joined; and (4) heating (1200 to 1600°F) by oxyacetylene flame, induction or resistance heating, or by furnace heating. Aluminum or alloys that melt below 1250°F cannot be joined by silver brazing.

Solder. The term "solder" or "soft solder" usually refers to the tin-lead alloys of from 15 to 60 per cent tin. Additions of antimony, bismuth, and cadmium may be made to reduce cost or to obtain special properties. Soft solders are low-strength low-melting alloys (400 to 600°F) used for joining a large number of the common metals and alloys. The higher grades of solder contain the larger amounts of tin. Solder for electrical work may contain 60 to 90 per cent tin; the most common solder for general purposes contains 50 per cent tin. Wiping solder (so named because of the application technique) contains 40 per cent tin; low-grade solder for filling dents in automobile bodies contains 15 per cent tin. During the war emergency, tin was conserved by resorting to high-lead alloys for many soldering applications. The atmospheric corrosion resistance of tin-lead solders is in general satisfactory. Under more severe conditions, or when solder is used on copper or monel, accelerated corrosion may occur. Success in the use of soft solders depends on obtaining a clean surface on the metals to be joined, applying the proper flux, and heating the metal to the melting point of the solder. The heating operation may be accomplished by wiping the joint with semiliquid solder, by use of a soldering iron, blowtorch, solder bath, resistance or induction heating.

Because solders are inherently weak material, soldered seams should be strengthened by crimping, interlocking, or riveting before soldering.

Tantalum. Tantalum is a white, lustrous metal of high specific gravity—16.6—possessing unusual resistance to acid corrosion. It is practically chemically inert toward all materials except hydrofluoric acid and concentrated caustic. It is ductile and malleable and can be drawn into fine wires, rolled into thin sheets, or formed into a variety of sizes of tubing. Tantalum is welded successfully by the electrical-resistance method. Owing to its affinity for gases, the welding is usually carried out either under the surface of carbon tetrachloride or in the presence of a 100 per cent carbon tetrachloride vapor. It possesses the unusual property, owing to its natural inertness, of remaining clean under a variety of chemical service conditions. This permits its use in certain chemical equipment where heat transfer is a paramount factor and where the over-all economics will justify a metal of the high cost of tantalum.

Stainless Alloys. Stainless alloys may be divided, for purposes of approximate classification, into three groups: (1) ferritic alloys, which are essentially iron-chromium alloys and in certain cases with small amounts of nickel and molybdenum, the alloying element amounting up to 30 or 36 per cent of the total and with varying amounts of carbon; (2) austenitic alloys, containing from 16 to 25 per cent of chromium together with 7 to 20 per cent of nickel (these may contain up to 1 per cent columbium as a stabilizing agent); and (3) complex alloys, containing, in addition to the chromium and nickel, varying amounts of molybdenum, silicon, copper, manganese, each alone or in admixtures. All the alloys in these three classifications are quite resistant to oxidizing agents, and certain ones find wide use under corrosive conditions involving sulfuric acid, nitric acid mixtures, and nitrates. Table 25-1 contains a great deal of information that is pertinent to the various grades of stainless alloys.

1. Ferritic alloys are used in nitric acid service and certain general oxidizing service conditions. The composition range in this classification is broad. The low end of the range begins in commercial-alloy composition at 11.50 to 13.0 per cent chromium together with 0.12 maximum carbon and extends upward to an alloy with 30 per cent chromium and 0.35 maximum carbon. All the alloys in this range, *i.e.*, AISI types

---

* Hardenability decreases as (a) chromium content increases and (b) carbon content decreases.

† Embrittlement and loss of corrosion resistance occur if drawn in range of 900° to 1100°F.

‡ Welding characteristics improved by presence of certain elements, such as Ti and Cb, which render the material non-air-hardening.

403, 416, 430, 444, 329, and 446, are weldable with some difficulty and require a prescribed heat-treatment subsequent to welding in order to restore full stainless qualities. The handling, fabrication, and heat-treatment of these grades may be carried out on most plants, but previous experience is necessary for best results. The alloys in this classification are usually available in a wide variety of commercial shapes and find application in chemical plants within the scope of the physical and chemical properties of the materials.

2. Austenitic alloys are widely used in nitric acid service and certain general oxidizing service conditions. Austenitic alloys in the more conventional compositions contain the essential chromium and nickel (see Table 25-1 for types 304, 303, 302B, 316, 317, 309, 310, 311, 321, 325, and 347; types 321 and 347 contain addition agents, titanium and columbium, respectively, which have a marked effect on the heat-treating procedures and resulting properties). The welding properties of the austenitic alloys are much better than those of the ferritic types. The increased alloy content of the austenitic types results, under the majority of service conditions, in an increased resistance to corrosion. Several of the austenitic grades overlap in application, but certain ones, such as types 316 and 317, possess particular resistance to acetic acid hot and cold, with or without small amounts of sulfuric acid. Tests should always be run in advance under the specific service conditions. All the above compositions referred to are available commercially in some forms. However, the number of shapes is sometimes limited. If the amount required is less than enough to warrant a special processing lot, it is desirable to select a suitable alternate material on the basis of the properties and characteristics of other austenitic materials described in Table 25-1.

3. Complex austenitic alloys for sulfuric acid and certain sulfuric-nitric mixtures are closely related to the conventional austenitic alloys and differ principally in the increased amounts and number of metals added. These constitute a large number of complicated alloys, both cast and wrought. The addition of molybdenum and copper, usually together with manganese and silicon, to the conventional chromium-nickel austenitic alloys imparts increased corrosion resistance, particularly under corrosive conditions involving sulfuric acid, sulfites, and sulfates. Numbers of commercial alloys of this general type are available in cast and wrought forms. Often these alloys are made up into standard equipment such as pumps, valves, centrifuges, and filter frames by the manufacturer and are recommended by the producers for specific plant service conditions. Notwithstanding this confidence on the part of the manufacturer, it is desirable and even necessary that the customer conduct corrosion tests under the specific plant conditions in order to ensure that no unforeseen condition exists which will shorten the life of the equipment.

TRADE WASTE DISPOSAL*

BY H. L. JACOBS

Chemical Engineer, E. I. du Pont de Nemours & Co., Inc.

INTRODUCTION

This section is a general guide to the problem of proper treatment and disposal of industrial wastes and not a discussion of the solution to specific problems. Rarely are two industrial waste problems alike in all details, and each one should, therefore, be handled as an individual situation.

The field of industrial waste treatment is relatively new compared with the amount of study that has been devoted to the treatment of sanitary sewage. It is true that a considerable number of problems have been solved to the satisfaction of pollution-control authorities, but many more exist which have not been studied or for which reasonable treatment methods have not been developed. This situation is partially due to the feeling on the part of most plant managers that waste treatment will add to the cost of their products and should, therefore, be avoided as long as possible. While this may be true in many cases, it is also true that many waste problems have been solved by the recovery of materials at a profit. As a matter of fact, in a few instances, the value of the recovered material has become extremely important in reducing the manufacturing cost and hence the selling price of the primary product.

The time is rapidly approaching when all industries and municipalities will be required to meet rigid specifications for the quality of their water-borne wastes. It is to be hoped that these specifications will permit *reasonable* amounts of contamination to be handled by the self-purification abilities of the receiving waters. The movement to clean up the nation's streams has been progressing during the past 50 years. Legislative activity in the field of stream-pollution prevention has become vigorous since 1940. During the years 1943 and 1944, in spite of the burdens imposed by the Second World War, stream-pollution legislation was introduced in 27 of the states. In 12 of these, the existing laws were amended, while the states of Tennessee, Washington, Minnesota, and North Carolina covered stream pollution in their statutes for the first time. The state of Virginia has since followed suit. The creation of several interstate commissions, with the primary object of reducing the pollution throughout large drainage areas, has resulted. Such commissions are now functioning in connection with the Delaware, Potomac, and Ohio River basins.

On many plants provisions have not been made for the segregation and treatment of sanitary wastes from office buildings and change houses. In too many instances no thought of the ultimate necessity for treatment of these wastes was given at the time the sewerage system was laid out, and as a result, sanitary and industrial wastes are mixed indiscriminately prior to discharge. In certain cases the sanitary sewage can be treated with the industrial wastes to advantage, but in many others the proper procedure will necessitate segregation and separate treatment. The methods for treatment of sanitary sewage have become standardized, and no discussion of them is contemplated here. Advice should be obtained from the appropriate health agency before the problem is attacked. Nearly all states require that plans be submitted for approval to the state health department.

DEFINITION OF POLLUTION

A stream becomes polluted when waste matter is introduced in sufficient amounts to alter the water quality so as to make it unsuitable for domestic or industrial supply or for the proper support and growth of marine life. This may occur because of the presence of dissolved salts or organic matter, materials carried in suspension, floating oils, acids, alkalies, or toxic substances.

---

* Superior numbers indicate specific references listed at the end of this section.

EFFECTS OF VARIOUS WASTES

Acids and Alkalies. Mineral acids such as sulfuric, nitric, and hydrochloric will neutralize the natural alkalinity of the receiving waters with a resultant lowering of the pH value. Below pH 5.0, the more delicate fish such as trout and bass will be adversely affected, while at values below pH 4.0 nearly all types will die. At the same time, the effect on the food supply of the fish will be adverse owing to the decrease or death of marine organisms. Sulfuric acid or sulfates will increase the permanent hardness of the receiving waters, while hydrochloric acid or chlorides may render the water nonpotable even though the proper pH is maintained by the addition of alkali. The presence of mineral acidity in a stream creates a sterilizing effect which interferes with normal biological activity tending to purify the water of its organic content.

Any discharge of alkali which increases the pH value of the receiving waters above 9.0 will also prove detrimental to fish life.

Suspended Solids. Solids in suspension in a plant effluent may prove detrimental whether inorganic or organic in character. If they are heavy enough to settle out in the relatively low velocity of the receiving waters, bottom life will suffer, and the stream characteristics will be altered. If the settleable material is organic in nature, anaerobic decomposition will take place with the production of hydrogen sulfide and methane gases with consequent foul odors. In navigable waters, channels will be filled up, and dredging will be required more frequently.

Floating Matter. A common complaint in regard to certain effluents is the presence of floating matter Greases, oils, and tars are sometimes discarded to the sewer system and eventually show up as contamination in the receiving waters. These materials, particularly oils, spread out in very thin films on the water surface and interfere with the normal oxygen absorption from the atmosphere. Usually they are stable compounds which oxidize slowly, and the effect is, therefore, of long duration. Fish life may be damaged either by suffocation or at least by the absorption of tastes and odors in the flesh so that its value as human food is impaired. Floating oils will also be damaging to the paint on boats. In general, the source of such pollution is easily traced and may become a beacon which will lead the authorities to other sources of contamination.

Organic Matter. The organic matter present in clean and polluted streams is oxidized by the dissolved oxygen in the water with the formation of simpler compounds such as water, carbon dioxide, sulfates, and nitrates. This process of oxidation takes place with the assistance of bacteria which are present in most receiving waters. These bacteria are introduced by the discharge of raw or unsterilized sewage or by pickup of soil bacteria by storm waters. If the quantity of organic matter is small, the rate of reduction of dissolved oxygen will be overcome by the normal reaeration of the water. When this is the case and the dissolved oxygen remains above 5 ppm, no damage results, and the water is not considered to be seriously polluted. In many cases, however, the organic load is sufficient to cause serious depletion of the dissolved oxygen. At oxygen values below 5 ppm, the finer types of game fish cannot exist satisfactorily, and at values below 4 ppm, nearly all fish life will be affected adversely. When the dissolved oxygen content drops to 2 ppm and below, nuisance conditions are created, and foul odors are given off owing to anaerobic decomposition of the organic matter.

The term in general use for representing the effect of organic matter in the depletion of dissolved oxygen is known as the "biochemical oxygen demand," usually contracted to BOD. The BOD of a given effluent can be measured by means of a standard test which has been developed for sewage effluents. This same test can be applied to industrial wastes. The test consists of diluting to various degrees samples of the waste water with a well-aerated dilution water which has been "seeded" with a small quantity of sewage. The several dilutions, together with the required "blanks," are incubated at 20°C for 5 days, at which time the dissolved oxygen is determined by standard titration methods. The difference in oxygen content of the samples and "blanks" is then calculated to parts per million in the original waste and reported as BOD.[1]

Toxic Materials. Many materials that are toxic to humans and other animals are also detrimental to marine and bacterial life. Metallic or alkali cyanides in concentrations as low as 0.2 to 0.3 ppm will kill fish and will interfere with and sometimes completely inhibit digestion of sewage solids in sewage-treatment plants.

Soluble copper compounds are effective sterilizing agents and in concentrations as low as 0.25 ppm will be lethal to fish life. Sanitary sewage containing as much as 1.0 ppm of copper cannot be treated satisfactorily by biological processes because of the sterilizing effect on the bacteria.

The list of compounds that are detrimental to fish and bacterial life is a long one and includes such materials as hydrogen sulfide, chlorine, barium chloride, chromic acid, aldehydes, benzene, gasoline, and many others. Much information on the allowable limits for various compounds with respect to fish life is contained in a government publication,[2] and a large amount of work on fish mortality has also been carried out by the Michigan Experiment Station.

Taste and Odor Producers. Some compounds, usually organic in nature, are capable of producing serious taste and odor nuisances in potable water supplies. Of these the most common are phenol and some of its derivatives contained in wastes from coke-oven operations and certain other chemical processes. Phenol by itself can be tolerated by the human system to the extent of several parts per million, but upon chlorination the presence of a few parts per billion makes the water unpalatable. Many other compounds will impart undesirable tastes or odors which can be classed as "musty," "saline," "earthy," etc. It is frequently necessary for the water-plant operator to resort to excessive chemical dosage or to treatment of the water with activated carbon in order to produce a palatable water. Frequently the water consumer must put up with poor-quality water for a time because of the inability of the water-plant operator to eliminate completely the taste and odor.

PLANT SURVEY OF WATER-BORNE WASTES

Measurement of Volume. Importance of accurate measurement of the volume of the contaminating effluent cannot be stressed too greatly. Without such measurements, very little progress can be made in the study of the proper treatment method to be applied or of the quantity that may be discharged without damage to the receiving waters.

The method used to obtain accurate volumetric measurements will vary with the physical nature of the plant and process. In cases where the operation is compact and effluents are all collected and discharged through a single sewer, meter readings of the plant water consumption will sometimes suffice. In a complicated layout with several effluents entering a common sewer or with a sewer system split up into multiple outlets, it will be necessary to devise special methods for accurately determining the individual and over-all flows.

Determination of flow in an underground sewer is difficult to carry out. If the size and slope of the sewer are known, charts[3] are obtainable that will give the flow at various depths. If a location can be selected at which the flow level is unaffected by turbulence or velocity increase at the entrance to a manhole, depth measurements will provide reasonably accurate flow rates. For continuous readings, a low-pressure recorder can be used to record the pressure required to bubble air through the liquid in the sewer. Pressure recorders capable of reading less than 1 in. of water pressure can be obtained. The air stick used for this purpose should be carefully made so that the air opening will not be constricted at the bottom of the sewer. It is a good idea to place the opening at a known distance from the bottom of the pipe and to correct the readings accordingly so that the pipe can be rested on the inside bottom of the sewer at the exact center line. In using this method it is important to know that the sewer line ahead of the point of measurement is free of sediment or obstructions.

Any number of other standard methods of flow measurement can be applied when the proper conditions prevail. For individual discharges from pipes under pressure, some type of orifice plate may be suitable. For sewer lines, a weir box with a square, V-notch, or Cippoletti weir may be applicable. In order to obtain accuracy with a weir, it is necessary to observe carefully the dimensional requirements so that the *vena contracta*, approach velocity, and other factors will be correct. If measurements are to be made of an effluent containing appreciable solids in suspension, the installation should be made with a gate or opening at the bottom of the weir plate, or the weir plate should be removable so that the solids may be flushed out from behind it. Perhaps the biggest disadvantage of the weir is the relatively high head loss which must be overcome.

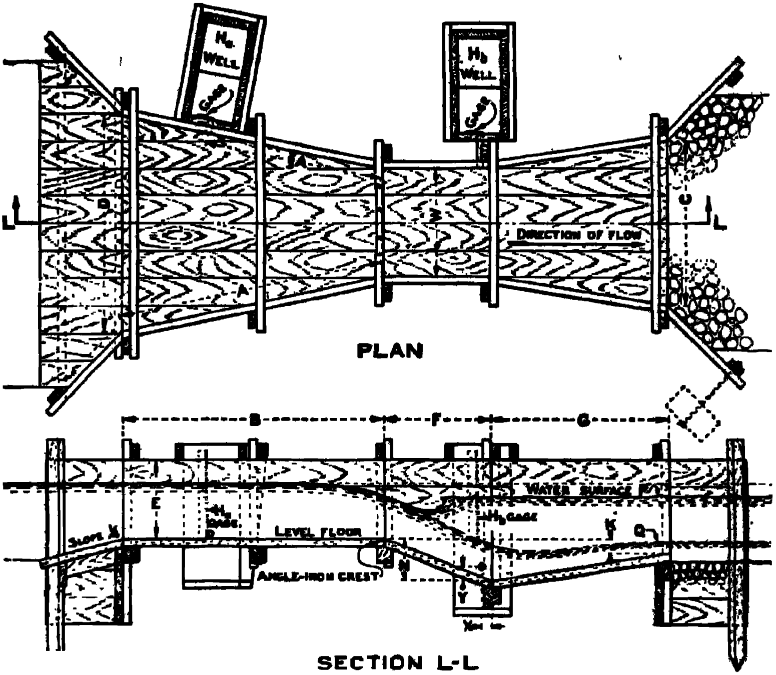

Fig. 26-1. Parshall flume.

The most satisfactory flow-measuring device for installation in a sewer line is the "Parshall measuring flume" (see Fig. 26-1). This flume was developed and tested by R. L. Parshall at the Colorado Experiment Station. It was developed primarily for measuring flows in irrigation ditches, but it is finding increasing use in sanitary sewage and industrial-waste-treatment plants. Its accuracy is sufficient to meet practical needs, and there is no point at which solids can collect and settle. Head loss is lower than for any other type of open measuring device. Flume liners made of sheet iron can be purchased in almost any required size. Fabrication of a liner from stainless-steel sheet which can be electric-welded is relatively simple. The easiest method for constructing the flume is to use the liner as the inside form for a concrete structure, leaving it in place for permanent use. For temporary use, wood construction is satisfactory. Complete details of construction and operation can be found in Reference 4.

Sampling. During the initial stages of a waste-disposal problem, grab samples are helpful for a quick analysis of the situation and for guides to a more careful sampling program. In most cases it is necessary to establish sampling procedures that will yield representative samples. If the problem is complicated, it may prove necessary for sampling to extend over a considerable period of time, and it will be most practicable to install continuous sampling equipment. It is beyond the scope of this section to cover the various means for obtaining such samples, but the equipment should be designed so that sampling rates are correlated with the flow. Where a substantial head loss can be taken, various types of splitting devices can be installed which will divert a small proportion of the total flow to a suitable container. For use with weirs or Parshall flumes, mechanical rotating samplers which will dip proportionate samples from the head chamber and lift them to a receiver can be purchased or built. One such device is known as the "Trebler sampler." Proportioning pumps can also be used in conjunction with flowmeters to draw off representative samples.

Analyses. It is rarely necessary to analyze a particular plant effluent for all the constituents listed below, but it is wise to have several complete analyses made of the over-all plant discharge so that the effect of the wastes on the receiving waters can be accurately estimated. In extreme cases of pollution, it may also be necessary to sample and analyze the receiving waters above and below the point of discharge. Usually, however, the necessity for correction of a waste discharge is created by a complaint from a downstream consumer, by fish mortality, or by an obviously unsatisfactory condition below the outfall, and the offending contaminant can be traced by the effect it creates. The analytical tests should include any of the following that will help in locating it:

1. Solids, suspended
2. Solids, total
3. Solids, volatile
4. Solids, fixed
5. pH
6. Acidity or alkalinity
7. Color
8. Grease or oil
9. Biochemical oxygen demand (BOD)
10. Oxygen-consumed value

Although the test for "oxygen-consumed value" has been used for years, no correlation exists between the values obtained in the test and the oxygen consumption that the waste will exert on the receiving water. The test for BOD is to be preferred and is rapidly becoming the criterion of organic pollution used by stream-control authorities. The "oxygen-consumed" test can be used to advantage in rough determinations of the dilution ratios that should be used in performing the BOD test.

In carrying out the analytical work the methods outlined in "Standard Methods for the Analysis of Water and Sewage," published by the American Public Health Association, should be followed. The BOD test is the only one of the above in which special apparatus and techniques are involved. With certain wastes it is found that chemicals are present that are toxic to bacteria, and consequently, the correct BOD will be difficult or impossible to determine. In such cases, the wastes must be investigated for the presence of known bactericides.

WASTE RECOVERY AND UTILIZATION

Although no two waste-disposal problems are alike in all respects, the approach to their solution should start along recovery lines. Frequently the recovery of values will prove to be a relatively simple matter when a thorough sampling and analytical program has located the major sources and points of discharge of the wastes.

The first step in the recovery program should be to check every possible outlet where wastes can enter the sewer system inadvertently. This check should include such obvious points as pump glands, pipe joints, and improperly tightened seals on pressure equipment. Frequently it will be found that a general tightening up or the elimination of "sloppy" operating habits will result in greatly improved conditions. Sometimes materials are deliberately thrown into the sewer when they could just as well be returned to process or put through a special treatment to convert them to a salable though substandard product. In any plan for general improvement of plant practices, it is wise to institute an educational program for supervising and operating personnel to advise them that an investigation of means for reducing contamination is under way and of the steps that have been taken in furthering the program. Possibly some valuable and usable suggestions will be forthcoming from both groups. In so far as preventable contamination is concerned, the cooperation of the operators is essential.

After the proper steps have been taken to decrease to a minimum the preventable waste, a thorough study of the process or processes responsible for the remaining contamination should be made. In addition to an engineering analysis of the process to determine optimum operating conditions with respect to losses, yield studies should be made under all feasible operating conditions in order to determine whether or not changes in temperatures, time cycles, reflux ratios, concentrations, etc., will result in decreased losses to the sewer. Equipment is often operated for such long periods at high throughputs that the rates for which it was designed are forgotten. While it may be economical to run certain equipment at higher than rated capacities, it is usually done at the expense of yields. It may be cheaper to enlarge the equipment, thereby reducing losses, than to install collecting and treating equipment to condition the wastes prior to discharge.

Wastes that cannot be eliminated at the source can sometimes be recovered for reuse or for sale on the outside. Sulfuric acid can be recovered economically by concentration if it is available at strengths of about 20 per cent H_2SO_4 or higher. If a use can be developed for a strength lower than that of commercial grades, strengths under 20 per cent can be considered for recovery possibilities. Three commercial acid concentrators are in general use today: the Simonson-Mantius vacuum evaporator, the du Pont falling film concentrator, and the Chemico drum-type concentrator. The first two operate under vacuum and are heated indirectly with high-pressure steam, although Mantius units utilizing hot oil for heating are available. The Chemico concentrator operates at atmospheric pressure with concentration being obtained by the passage of hot combustion gases through the acid. All these concentrators will successfully produce sulfuric acid of 92 to 93 per cent H_2SO_4 content. The falling film unit is applicable to the recovery of relatively clean acids, while either the Mantius or the Chemico will handle sludge acids satisfactorily. In calculating the economics of recovery by concentration, it should be recognized that acids lower in strength than that mentioned above can be considered when neutralization is the alternative since the cost of the latter will be avoided. If the sulfuric acid is contaminated with inorganic sulfates, these will usually precipitate at some intermediate strength and can sometimes be removed by settling, centrifuging, or filtration. If the removed salts have to be washed, the washings can be returned to the concentrator. If undesirable organics are present, they will sometimes be destroyed during concentration. If not, this result can usually be accomplished by holding the final acid at a high temperature for a required time. Destruction of the organic matter results in the decomposition and consequent loss of a certain amount of the sulfuric acid.

The usual method for recovering a usable grade of nitric acid is to mix it with concentrated or fuming sulfuric acid and then to distill the nitric acid. The sulfuric acid retains the water which is then removed from it by the usual methods of concentration. Sufficient sulfuric acid must be used to yield an acid of 70 to 72 per cent H_2SO_4 after nitric removal.

Methods for the recovery of hydrochloric acid are more complicated since dilute acids must be concentrated to the constant boiling mixture of 20.24 per cent and then that mixture distilled and condensed.

Organic acids are usually recovered by distillation or fractionation. In some cases it may be possible to saponify the acid with caustic and to effect a separation of the soap. The organic acid may then be recovered from the soap by treatment with a mineral acid such as sulfuric. It may also be possible to form a calcium soap of the organic acid which will separate more easily than the sodium soap. Organic acids are often a troublesome source of BOD, and neutralization does not correct that undesirable feature.

The conversion of the waste acid to a useful mineral salt should receive consideration before thoughts of recovery are abandoned. Satisfactory outlets can sometimes be developed for such common salts as ammonium nitrate, ammonium sulfate, ammonium chloride, sodium nitrate, and sodium sulfate. The concentration and crystallization of the neutral salt may present less of a problem than the recovery of the corresponding acid.

TREATMENT METHODS

Removal of Suspended Solids. The type of solids contained in the waste discharge will determine the line of attack to be followed in correcting the quality of the effluent. If it is a valuable or useful material and is not badly contaminated with other matter, steps should be taken to retrieve it before it reaches the receiving waters or even before it becomes mixed with other plant wastes. The process from which the material is lost should be examined to determine whether or not the recovered solids can be safely returned to it at some point. Obviously, plain sedimentation should be given primary consideration. Simple laboratory tests will provide sufficient information to determine such possibilities. If the results are promising, consideration should then be given to the type of settling tank that will be most suitable. The most important problem, aside from space requirements, is the one of selecting the proper solids-collecting and -removal equipment. If the solids are relatively heavy and will not be adversely affected by violent agitation, a centrifugal pump may be used for removing the underflow from the sedimentation tank, and the type of collecting mechanism is not important. If the recovered solids require careful handling, equipment should be selected that will not subject them to abrasive action. Plunger and diaphragm pumps are better selections for such service. Standard sedimentation equipment is manufactured by such companies as Dorr, Permutit, Link-Belt, Chain Belt, and others. Should it be desired to concentrate the solids still further, consideration should be given to filtration or centrifuging, depending on the nature of the solids. In many instances, filtration or centrifuging of the unsettled waste will prove effective.

If a clear effluent is required and if it cannot be obtained by sedimentation, flocculating agents such as alum or iron salts may prove helpful. Selection of the proper agent may be dictated by the nature or degree of contamination which the recovered solids can stand before their value as recovered material is lost. The selection of the best coagulating agent is again a matter for laboratory tests to decide. Alum will usually work well in the pH range of 6.0 to 8.0 but has the disadvantage of creating a rather light floc which does not settle too rapidly. Iron salts such as ferric sulfate, ferric chloride, and chlorinated copperas have the advantages of weight and a somewhat wider pH range for successful application.

In some cases, the solids in the effluent will be of such a nature that recovery is not warranted. When conditions require a clear effluent, these cases can be most easily solved by the use of a settling pond or lagoon of the largest practical size. If low-lying ground is available, it may be surrounded by an earth dike to form the pond. It is a good idea to divide the pond into two equal parts with a center dike, so that one-half of it can be drained and cleaned when necessary.

Neutralization of Acids and Alkalies. After all recovery possibilities have been investigated, there remain those wastes which must be neutralized prior to disposal. If the material is an alkali, the problem is relatively simple since sulfuric acid is the cheapest acid for such a purpose and can be conveniently shipped, handled, and fed in standard equipment. If the resulting neutral salt is insoluble at the concentration employed, additional dilution should be introduced, or provisions should be made to remove the precipitate from the effluent.

In the neutralization of waste acids, the cheapest form of alkali which can be purchased will be high-calcium or dolomitic limestone, hydrated lime, or quicklime. Typical analyses of good grades of high-calcium and dolomitic limestones are given in Table 26-2. When these stones are calcined to make quicklimes and are then hydrated, the calcium and magnesium ratios are unchanged. Hydration of a dolomitic quicklime does not result in a mixture of calcium and magnesium hydroxides, however, because the magnesium does not hydrate to an appreciable extent at atmospheric pressure. Whether for this or some other reason, it is a fact that dolomitic limes and limestones require a longer time to react with acids than do the high-calcium varieties.

Table 26-2

	High-calcium	Dolomitic
Calcium carbonate ($CaCO_3$), per cent	94.5	54.0
Magnesium carbonate ($MgCO_3$), per cent	1.0	42.0
Iron and aluminum oxides, per cent	1.0	1.0
Acid insoluble, per cent	3.5	3.0
Total, per cent	100.0	100.0

Limestone Beds. With certain problems, limestone beds for acid neutralization are convenient, successful, and highly desirable. The flow of solution may be upward or downward through the bed. In any case, the tank or structure confining the bed should be provided with a false bottom or free space below the bed where unreacted limestone and inert matter may collect. This free space must be flushed out periodically to remove the sediment. The acid solution must be relatively clear in order to prevent clogging of the bed. The depth of limestone in the bed will depend on the flow rate through it and the pH value desired in the effluent. If the proper precautions are taken in sizing the installation, excellent results can be attained with very little operating attention. No control equipment is required, and flow rates need not be controlled carefully if the bed has been designed to accommodate the maximum. The pH of the effluent will rarely exceed 5.0, but proper aeration of the effluent to drive off CO_2 will result in pH 7.0 or higher.

Limestone beds are ideally suited to the neutralization of *hydrochloric* and *nitric* acids when the quantities are not too great. When large quantities are to be handled, the size of the bed approaches the point where special design is entailed to ensure proper distribution of the solution, or the flow must be split to multiple beds. The design problems are surmountable, but the more complicated layouts can become very expensive. Flow rates and acid concentration of the feed will vary inversely, and insufficient data have been reported to establish their true relationship for varying depths of bed. It can be said, however, that passage of 2 gpm per sq ft of bed area of 5 per cent nitric or hydrochloric acid through a 6-ft bed of limestone will yield satisfactory neutralization. Stronger acids may be neutralized in this manner, but difficulties will be encountered with foaming. To determine the necessary design factors, it is much safer to carry out small-scale tests.

The neutralization of *sulfuric* acid involves more severe limitations because of the low solubility of the resultant calcium sulfate. The upper limits of acid concentrations are 0.3 per cent H_2SO_4 for high-calcium limestone and 0.5 per cent for dolomitic. Above those strengths, the stone will become inactivated because of the deposition of calcium sulfate. If it is impractical to dilute the feed acid to the required concentration, another neutralizing agent should be selected. Figure 26-2 indicates flow rates and bed depths for ¾-in. lump dolomitic limestone and 0.3 per cent sulfuric acid. These curves are also indicative of results that can be obtained with high-calcium limestone at the lower acid strength, but here again it will be safer to run tests with the actual acid and limestone that are concerned.

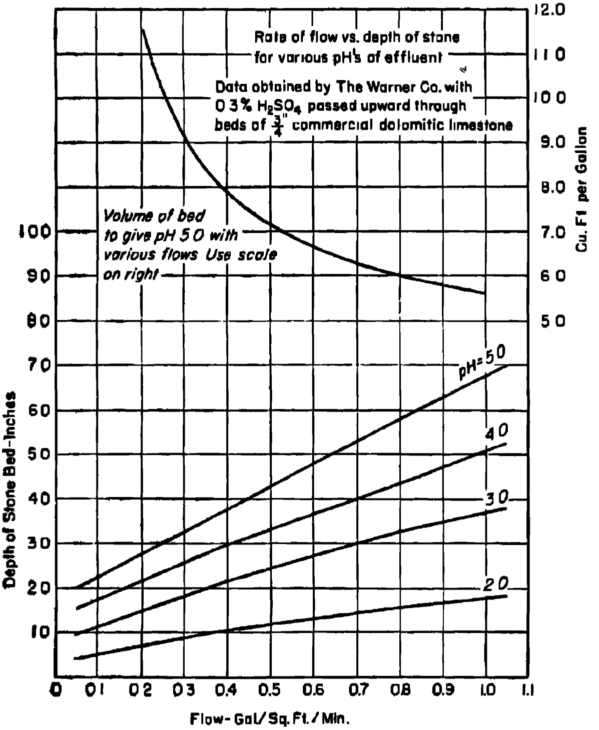

FIG. 26-2. Limestone bed performance. (*Warner Company.*)

Very occasionally, *hydrofluoric* acid may have to be disposed of by neutralization. The solubility of calcium fluoride is so low that the use of limestone for this purpose is impractical. Besides, the high toxicity of fluorides in general will usually prevent their disposition as water-borne wastes. The calcium fluoride should be precipitated with lime and removed as a sludge for disposal on a dumping ground.

Organic acids will lend themselves to neutralization in beds of limestone when the resultant calcium salts are relatively soluble. It should be remembered, however, that the BOD of the organic radical is unaffected by neutralization and that it may still become an objectionable waste.

Ground Limestone. Limitations imposed on the use of ground limestone for acid neutralization are rather severe, although it will find application in certain cases. These are confined to situations where the required limestone feed rate can be predetermined. Control of the feed by means of a pH instrument is not feasible for two reasons: the reaction time is too long, and the lack of active alkali plus the formation of CO_2 limit the pH rise. With dilute acids and with a limestone ground to pass a 20-mesh screen, reaction times of 30 to 60 min are required when the theoretical quantity of high-calcium limestone is used. Dolomitic limestones react so slowly that their use in the ground form is rarely worth consideration. In cases where the quantity of the discharged acid can be controlled, the use of ground limestone is practical. The material in the screen size mentioned will handle and feed with ease provided the moisture content is below 1 per cent. It can be stored in silos or bins without hanging up or becoming caked, and it is easily removed with a screw conveyor or other type of feeder. In finer sizes, however, it loses this characteristic and approaches hydrated lime in difficulty of handling. Facilities for retaining the acid-limestone mixture in a well-agitated state for at least 30 min should be provided. This may take the form of an agitated tank or tanks, a series of baffled flumes, or, where conditions permit, a sewer line at the proper slope and long enough to satisfy the retention requirements. Retention time may be shortened materially by utilizing an excess of stone, but this usually calls for the addition of facilities for the removal of the unreacted material. One should not forget that sulfuric acid requires dilution to 0.3 per cent before successful neutralization can be accomplished with limestone. Figure 26-3 shows reaction-rate curves for three different ground limestones. The stones were used in laboratory tests to neutralize mixed acid containing approximately 3,000 ppm H_2SO_4 and 2,600 ppm HNO_3. It is obvious that sample *C* was superior in reaction rate to *B* and *D*. The curves emphasize the importance of small-scale tests with the actual materials to be used in the plant.

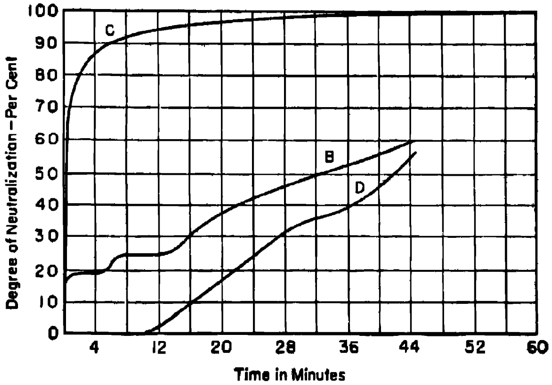

FIG. 26-3. Limestone reaction rates.

Hydrated Limes and Quicklimes. These materials are considered under a common heading since the chemical form in which they are used for neutralization is the same. Quicklimes must be properly hydrated before use. Quicklime should be considered whenever the neutralizing job is of sufficient magnitude to warrant the expense of slaking equipment and the operation of it. Quicklimes have higher neutralizing values than their corresponding hydrates to the extent of about 28 per cent for high-calcium and 14 per cent for dolomitic (see Table 26-3).

Table 26-3

Material	*Equivalent H_2SO_4, lb per lb*
High-calcium limestone	0.93
Dolomitic limestone	1.06
High-calcium hydrate	1.26
Dolomitic hydrate	1.63
High-calcium quicklime	1.68
Dolomitic quicklime	1.85
Calcium oxide (100%)	1.75

Delivered costs of quicklimes and hydrates in bulk are about the same per net ton. An advantage for quicklime is that bulk shipments are common, while hydrate is usually shipped in bags at a premium of about $1 per ton. Quicklime is more dangerous to handle than hydrate since it must be kept dry, and serious burns to the skin can occur if carelessness in handling is permitted. With the use of proper equipment for unloading and storing, however, these dangers are overcome, and the quicklime will generally store and handle better than hydrate.

The big advantage in the use of hydrated lime (purchased as such or prepared from quicklime) is that the alkali content is very active and is adapted to the use of pH-control equipment. In the usual neutralization problem, high-calcium lime will react completely in 1 to 2 min, while the dolomitic variety requires 6 to 10 min depending on the conditions under which it was calcined. Some authorities claim that shaft-kiln lime will react more slowly than that from a rotary kiln. The difference is not great, however. The curves in Fig. 26-4 indicate the reaction rates which may be expected with hydrated limes. Curve *A* represents a typical high-calcium lime; *B*, a dolomitic hydrate; and *C*, a dolomitic lime hydrated under 30 psi pressure. For the latter material it is claimed that the magnesium is completely hydrated. The tests supplying data for these curves were made with dilute acid containing 2,000 ppm H_2SO_4.

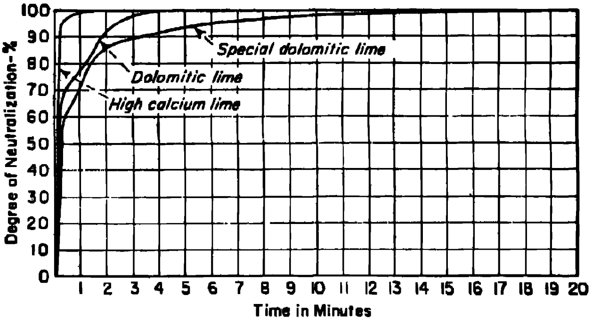

Fig. 26-4. Reaction rates of lime.

In general, hydrated lime will successfully neutralize acids at any reasonable concentration, and the pH of the resulting mixture can be controlled with automatic equipment. In some cases, particularly with sulfuric acid, heat is developed from the reaction and from the diluting effect of the added water. If the acid is too strong, the heat may be sufficient to dry out the reaction mixture until it becomes solid. This problem does not usually arise since acids of that strength can be recovered economically. Obviously, if the reaction products are not soluble, arrangements to separate and dispose of the solid matter will have to be made.

Figure 26-5 indicates equipment that will work satisfactorily where quicklime is to be used for acid neutralization. The quicklime in ground or pebble form is stored in a hopper or silo of either concrete or steel and is fed to the slaker at a constant rate by means of one of several types of feeder. Several types of lime slakers are made, and any of them sold by a reputable manufacturer will be all right provided it is properly sized. The principal requirement is that it must provide for the retention of the initial mixture at the proper lime: water ratio for a sufficient time and at a suitable temperature (95 to 98°C) to obtain complete hydration. A diluting compartment is usually provided in which the thick slurry is thinned to a solids content of 10 to 15 per cent for actual use. In cases where the demand is variable, it is necessary to provide intermediate slurry storage which can be utilized as a feed tank. The lime feeder and water valves to the slaker can be turned on and off electrically as needed by high- and low-level contacts in the slurry tank. The slurry is charged to the neutralizing tank by means of a centrifugal pump and a recirculating line. Recirculation of the slurry is required because of the necessity for maintaining a high velocity in the supply line to the control valve (at least 5 fps) to prevent stoppage. The control valve is regulated from a pH recorder controller, the electrodes of which may be suspended directly in the liquid in the mixing tank or installed in a chamber through which a portion of the overflow water passes. Several companies manufacture reliable pH-control instruments, but it is necessary to make sure that the control valve is of a type approved by the instrument supplier. The acid solution and lime slurry are introduced in separate streams to the downcomer of the neutralization tank. This tank is agitated by means of a sweep-type agitator and is equipped with baffles for turbulence. The volume of retained liquor is determined by the factors mentioned previously.

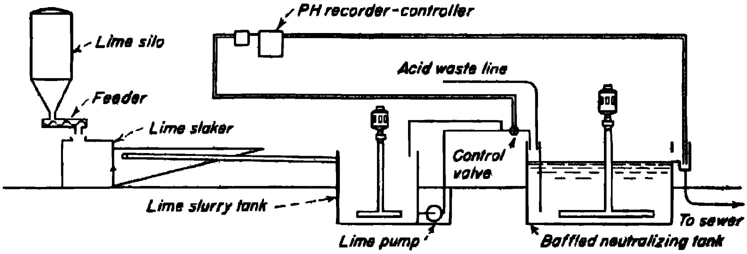

FIG. 26-5. Acid-neutralizing installation.

Color Improvement. If the effluent from a plant is sufficiently colored to affect the receiving waters adversely, the source should be determined and appropriate steps taken to correct the condition. Textile mills and dye plants are most frequently troubled by this problem, although tanneries, sulfite pulp mills, and some other industries must cope with it. The nature of the color will, of course, determine the steps which must be taken to remove or to destroy it. If the material is present as solid particles, means for settling it out or of precipitating and removing it must be devised. If it is in solution, as is usually the case, it must be absorbed, or its chemical composition must be altered in such a way that it is no longer noticeable. Sometimes simple adjustment of the pH prior to discharge will improve the situation since some dyes act as indicators.

The most positive approach will involve some form of chemical treatment either to reduce or oxidize the compound responsible for the color. The more common reducing agents such as SO_2 and the sulfites should be tried as well as acidification of the solution followed by the addition of metallic iron. The usual oxidizing agents consist of the dichromates, permanganates, hypochlorites, or liquid chlorine. The latter will be the most economical from the chemical-cost standpoint, although special precautions are necessary in handling it. If the color is due to a soluble sodium salt, it can frequently be converted to an insoluble compound by acidification followed by treatment with lime or some other alkali metal.

Floating Oils. Difficulty from floating oils can usually be overcome by the application of preventive measures at the equipment or process that contributes the contaminant. If the contamination cannot be prevented by reasonable means, the oil-bearing effluent should be isolated at the point where the smallest possible volume will require treatment. Once the oil has been mixed with the effluent water, the best method for separating it is to pass the effluent through a suitable oil separator where the liquid is retained at a low velocity such that the oil will rise to the surface where it can be removed by skimming. Formulas for optimum design of oil separators for use in the petroleum industry have been worked out (see Fig. 26-6).[4] These data as well as other valuable information are available in pamphlet form.[5] A line sketch of an oil separator taken from the pamphlet appears in Fig. 26-7.

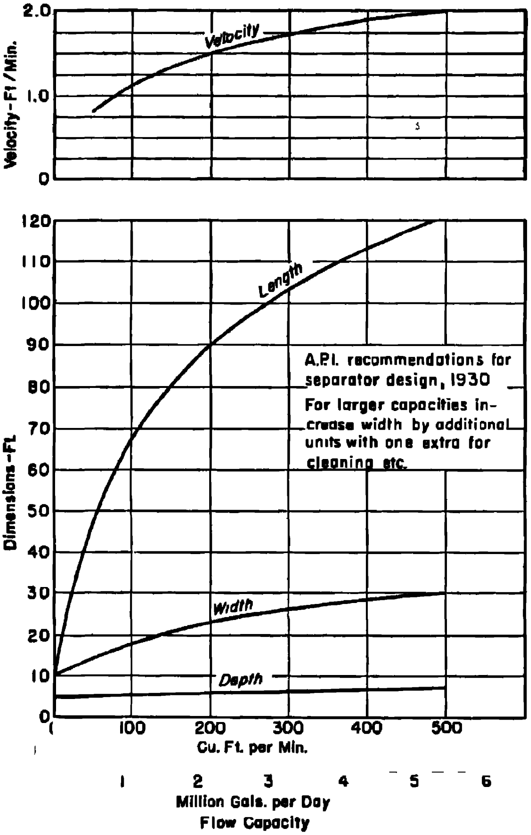

FIG. 26-6. API separator-design factors.

Problems will arise where oil is present in an emulsified or thoroughly dispersed condition. Oil separators are of no value in these cases unless steps are taken to "break" the emulsion beforehand. This cannot be accomplished by the same method in every case, but since the particles of oil are surrounded by a colloidal film containing an electrical charge, the job is one of neutralizing the charge or altering the nature of the film so that the oil particles will coalesce. Sometimes this may be accomplished by changing the pH of the water, by heating, or by the use of a coagulant. A laboratory investigation of the problem is essential.

Reduction of Biochemical Oxygen Demand. Biochemical oxygen demand (BOD) of an industrial waste can be due to organic matter in suspension and in solution. Material in suspension should be removed by methods discussed on pp. 1594 to 1595.

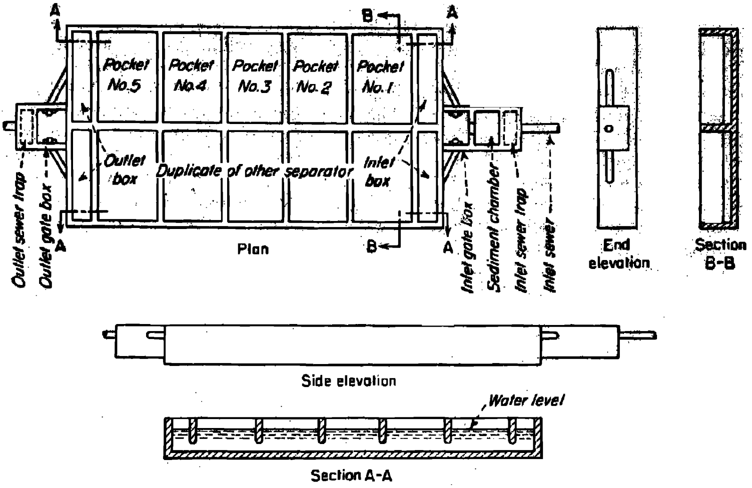

Fig. 26-7. Design of typical refinery separator.

Organic matter in solution requires treatment somewhat outside the usual experience of the chemical engineer. It is in the field of BOD reduction or destruction that a great deal of investigation is needed.

Some idea of the extent of the pollution created by various organic compounds can be gained from Table 26-4. The BOD values were determined in industrial laboratories during routine testing of plant effluents. Industries such as dyeing, beet-sugar extracting, canning, wood pulping, tanning, packing, and distilling are examples of those producing wastes characterized by high BOD values.

Perhaps the outstanding development in the industrial-waste-treatment field has been the adaptation of the trickling filter to the reduction of BOD content of industrial effluents. The trickling filter and its variant, the biofilter, were first applied to the purification of clarified sewage in which the BOD is present in solution and in the form of finely divided or colloidally dispersed particles of organic matter. Application of this principle has been widely used in the treatment of milk wastes and certain wastes from distilleries. At least one commercial biofilter is working satisfactorily in this country in the treatment of organic wastes from the manufacture of viscose rayon. The Dow Chemical Company at Midland, Michigan, has had a battery of four trickling filters operating for several years in the destruction of phenols in certain of their waste waters. Results of laboratory and semiworks scale tests indicate that

Table 26-4. BOD of Pure Compounds

Compound	Lb BOD per lb	Compound	Lb BOD per lb
Methyl alcohol	0.82	Sodium formate	0.04
Ethyl alcohol	1.00	Acetone	0.69
n-Propyl alcohol	0.47	Ethyl acetate	0.86
Isobutyl alcohol	0.07	Dibutyl phthalate	0.43
Formic acid	0.19	Butyl alcohol	2.04
Acetic acid	0.88	Phthalic anhydride	0.72
Methacrylic acid	0.89	Cornstarch	1.25
Methyl methacrylate	0.14	Casein	1.17
Calcium acetate	0.43	Gelatin	0.88
Formamide	0.00		

many problems involving organic contamination can be successfully solved by the use of trickling filters or biofilters. The latter will doubtless find wider application because of their ability to withstand "shock" loads as well as their greater flexibility in operation at variable flow rates.

A trickling filter is a bed of stone placed over a large surface composed of drainage tile or other liquid-collecting system. The stone is usually sized from 2 to 4 in. and should be of a variety that fractures unevenly. The underdrain system can be one composed of special tile members, or it can be a simple grid system for suspending the stone over a drainage space which is properly sloped to collect the liquid at a suitable point for discharge to a settling basin. The stone is built up to a depth of 5 to 8 ft and is surrounded by a wall or enclosure of wood, cement block, or concrete. The retaining wall can be eliminated by allowing the stone around the outer edge to seek its normal angle of repose. This naturally calls for greater bottom dimensions for the filter, and a larger quantity of stone must be used. The shape of the bed in plan may be square, rectangular, or round. Fixed or stationary distributors are used for square and rectangular filters, while rotary distributors are used with round filters. Round filters are usually installed in modern designs.

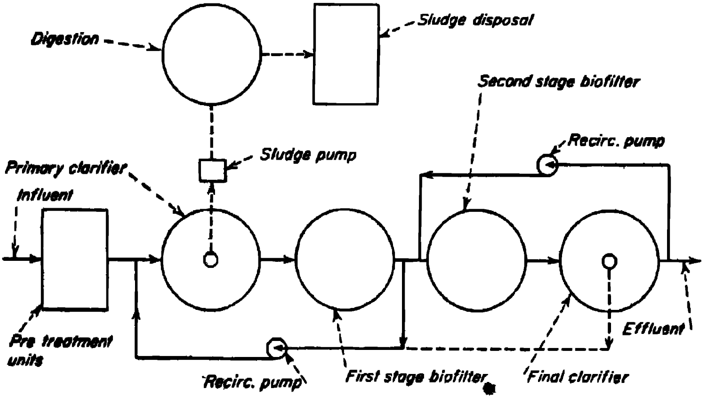

FIG. 26-8. Two-stage biofiltration.

The biofilter is a shallow trickling filter, and the details of construction are practically the same for each except that the depth of stone in the biofilter is held to 3 or 4 ft. In operation, the liquid is recirculated over the filter by means of pumps in varying amounts depending on the degree of reduction of BOD desired. The quantity of recirculated liquid will vary from one to ten times the volume of the feed. The sewage or waste being applied to the filter must be settled prior to application to avoid clogging of the interstices between the stones. Final settling of the filter discharge is also required, and if more than one filter is used in series, intermediate settling may be required. A line sketch of one type of biofilter installation is shown by Fig. 26-8. Several variations of equipment placement and recirculation practices such as parallel, series, and series-parallel are possible.

Trickling filters are operated on a once-through basis of the liquid being treated. The application rate for sanitary sewage and for organic wastes of comparable strength is usually set at 2 million gallons per acre per day, or about 45 gal per sq ft per day. At this rate, the BOD load with normal sewage will be 0.5 to 0.8 lb per cu yd of stone per day. Biofilters are designed for application rates as high as 30 million gallons per acre per day with BOD loadings up to 4.0 lb per cu yd per day. Owing to the low rate of application to trickling filters, the action is intermittent with alternating periods of wetting and drying of the film on the stones. With the biofilter, however, the object of the high application rate is to approach as nearly as possible continuous wetting. With rotary distributors, a short period of nonapplication between wettings is inevitable, although certain distributor designs permit liquid application approaching the continuous.

The functions of the filter are (1) to provide a medium upon which the purifying bacteria can grow and multiply; (2) to supply oxygen for use of the bacteria in oxidation of organic matter; and (3) to provide ample food for the bacteria continuously. The bacteria are present in raw and settled sewage, and it is necessary only to provide them with suitable conditions to carry out their functions. The bacteria establish themselves on the surface of the stone in the form of slimy growths. Air is drawn up through the bed by natural draft, and the applied liquor passes downward, spreading in a thin film over the surfaces of the stone, thereby coming into intimate contact with the slimes. The phenomena by which the organic matter in sewage is destroyed in passing through a biological filter are not definitely understood, but the nature of the process has been variously described as colloidal precipitation, absorption, and changes in surface tension. It is certain, however, that one function of the bacteria is to utilize the oxygen from the air in converting the complicated organic compounds into the simple end products, carbon dioxide and water. A portion of the ammonia and other nitrogen compounds end up as nitrates, nitrites, and free nitrogen. There is evidence to indicate that certain bacteria utilize organic nitrogen as a source of energy since a disappearance occurs as the sewage is treated.

Many organic compounds found in industrial wastes can be treated successfully for BOD reduction on trickling filters or biofilters. Most of the compounds listed in Table 26-4 have been treated on experimental filter units with BOD reductions of 70 to 75 per cent in most cases. In fact, any organic compound on which a successful BOD analysis can be carried out should lend itself to biological treatment. If the waste organics originate in chemical processes, they will probably be "sterile," and inoculation with sewage prior to biotreatment will be required.

In a short time after a biological filter has been put into operation, a "sloughing" or "unloading" of the slime growth occurs. In a trickling filter this action usually takes place intermittently, but in a biofilter it is practically continuous. This "sloughed" material contains a portion of the BOD which has been removed from the liquid as well as excess bacterial colonies. It is necessary, therefore, for this material to be removed from the filter effluent before it can be discharged to the receiving water. It is customary in sewage-treatment practice to settle out the slimes and pump them back to the primary sedimentation tank from which they are removed to the digestion tank. The sludge undergoes digestion under anaerobic conditions and is finally discarded as a dry solid after treatment on the sludge beds. In biological treatment of industrial wastes, final sedimentation and sludge digestion must be provided even though preliminary settling ahead of the biological filter is not required.

Disposal of Cyanides. The disposal of cyanide wastes is a problem largely confined to the metals industry, although it does exist in the coke industry and in some strictly chemical operations. The metal-plating industry uses the cyanides of copper, nickel, and zinc along with the alkali cyanides of sodium and potassium. The wastes are produced in two forms: spent plating or heat-treating bath and dilute wastes from the wash tanks. If disposal of the cyanides as a water-borne waste is practiced, the concentration of the cyanide as NaCN should not exceed 0.25 ppm in the receiving waters. Special precautions must be taken to assure that rapid and complete mixing with the receiving waters occurs so as to prevent the formation of zones of pollution which will be lethal to fish and marine organisms.

Strong wastes may be placed in disposal ponds for ground absorption and evaporation, but there is a real danger from contamination of underground water supplies. Solid wastes can be sent to the dumping ground, but, there again, a hazard exists unless the dump is located in a place inaccessible to the public and where rain will not carry the soluble matter to a stream. Ponding of dilute wastes for several months will result in the disappearance of the cyanide radical as oxidation and decomposition take place. The bottoms of such ponds should be sealed so that leakage does not occur.

Treatment of a cyanide solution with ferrous sulfate results in the formation of a corresponding ferrocyanide which lacks the lethal properties of the straight cyanide.

The ferrocyanides are generally highly colored salts and may cause complaints when discharged without further treatment to a receiving water. Unless a large excess of ferrous sulfate (500 to 600 per cent) is used, the resulting solution will not be completely free of cyanides. When molecular equivalents are used, the cyanide will not be reduced much below 50 ppm. The ferrous sulfate method should be used only under conditions where receiving-water quality is not critical.

Most cyanides will convert to hydrogen cyanide (HCN), one of the most lethal of gases, on being acidified with a mineral acid. This chemical reaction is used to advantage in one method of disposing of waste cyanide plating solutions. The wastes are placed in an acidproof tank, covered, and made airtight except for an exhaust stack. Air is forced through the liquid through perforated pipes laid on the bottom of the tank. Strong sulfuric acid (60 or 66°Bé) is charged to the tank through an overhead pipe after the solution to be treated has been run in. The rate of acid addition controls the evolution of the HCN gas, and the air agitation assists in driving it out of solution. The stack discharges the air–HCN mixture at a height sufficient to prevent toxic mixtures from reaching the ground. An induction fan discharges to the base of the stack to provide positive draft and additional dilution. This method is unsafe in congested areas, and the rate of acid addition must be carefully calculated and controlled.

The lime–sulfur method is frequently utilized for the treatment of strong cyanide solutions and waste cyanide solids from heat-treating installations. The solution is heated by steam and held at a temperature of about 60°C while commercial lime–sulfur solution is slowly added with continuous agitation. A yellow precipitate is first formed, and the end of the reaction is indicated by a permanent orange-red color. The precipitate can be settled and removed for disposal to a dumping ground. The supernatant liquor should be allowed to leach into the ground at a suitable location or discharge to the receiving water at a low rate, provided the volume is not too great.

Cyanides can be converted to cyanates by treatment with sodium or calcium hypochlorite. The alkali cyanates are relatively harmless to fish and will not revert to cyanides in the receiving waters. The metal cyanates are no more toxic than other compounds of the same metal. In using the hypochlorite-treatment method, care must be taken to maintain sufficient alkalinity to prevent the formation of the toxic gas, cyanogen chloride. It is customary to use a molecular equivalent of free alkali for each mol of cyanide calculated as NaCN. Oxidation of the cyanide to cyanate is the most positive method for the destruction of its toxic properties, and there are usually no remaining products requiring special treatment except copper or nickel under some conditions.

The Wallace & Tiernen Company has perfected a method for oxidizing cyanides which is a further development of the method just described.[6] According to unofficial reports, the process involves chlorination of the cyanide-bearing solution by means of a standard chlorinator with precautions taken to keep the pH of the resulting mixture above 8.5 at all times. The use of hypochlorite or chlorine will find particular application in the treatment of wash waters and other dilute wastes.

HEAT TRANSFER*

BY WARREN M. ROHSENOW, D. ENG.

Assistant Professor of Mechanical Engineering, Massachusetts Institute of Technology

There are in general three kinds of heat transfer: conduction, convection, and radiation.

Conduction is the transmission of heat by molecular vibrations from one part of a body to another part of the same body or from one body to another body in physical contact with it, without appreciable displacement of the particles of the body.

Convection is the transmission of heat from one point to another within a gas or a liquid by the mixing or circulation of the fluid. If the fluid is circulated by the action of gravity due to differences of density of the hotter and colder portions of the fluid, the process is called "natural convection"; if the fluid is circulated by a pump, blower, or other mechanical means, the process is called "forced convection."

Radiation is the transmission of heat in the form of electromagnetic waves. All bodies give off heat in the form of radiant energy. When this radiant energy falls on another body, part of it is absorbed by the body, and part of it is reflected. The difference between the amount of radiant energy which a surface gives off and the amount it absorbs from other surrounding surfaces which it "sees" is the net heat transferred by radiation.

In most cases the actual heat transfer is accomplished by more than one of these three types of heat transfer; however, in some cases the major part of the heat transfer is accomplished by one of the types, and the heat transferred by the other types may be neglected. For example, in the furnace cavity most of the heat transferred to the first row of boiler tubes is accomplished by radiation; in later tubes both convection and radiation heat transfer must be considered; in the economizer and condenser convection heat transfer is most important.

Most heat-transfer problems applied to a power plant are of a steady-state type. The operating conditions, such as temperature and pressure, do not vary appreciably with time, and the rate of heat transfer from or to a particular surface is constant with time. We shall consider only this type of problem—one of steady-state operation.

NOMENCLATURE

A = area of heat-transfer surface, sq ft

b = height of plate, ft

C = conductance, Btu/hr/sq ft/deg F

cp = specific heat at constant pressure, Btu/lb/deg F

D = pipe diameter, ft

D' = pipe diameter, in.

D_c = coil diameter, ft

F_{12} = angle factor

$\mathfrak{F}_{12}$ = factor relating angle factor and emissivity

G = mass velocity, lb per hr per sq ft of cross section occupied by fluid

g = 4.18×10^8 ft per hr per hr

h, h_v = local individual film coefficient of heat transfer, Btu/hr/sq ft/deg F difference

h_s = coefficient of heat transfer for scale deposit

$(h_v + h_r)$ = combined coefficient of conduction, convection, and radiation between surface and surroundings.

---

* Superior numbers indicate specific references listed at the end of this subsection.

k = thermal conductivity, Btu/hr/sq ft/unit temperature gradient, deg F per ft
L = length of pipe, ft
N = number of tubes through which fluid flows
q = rate of heat transfer, Btu per hr
r = radius, ft
t = temperature, deg F
t_s = condensing temperature of steam in a condenser
t_{w1}, t_{w2} = inlet and outlet temperature of cooling water
T = $t + 460$, temperature deg F absolute
U = over-all coefficient of heat transfer, Btu/hr/sq ft/deg F
V = average velocity, volumetric rate of flow divided by cross section filled by fluid, ft/sec
w = mass rate of flow, lb per hr
x = thickness of conductor or wall, ft
X = temperature rise of cold fluid ÷ inlet temperature of hot fluid minus inlet temperature of cold fluid
Y = factor that depends upon the surface arrangement of a heat exchanger
Z = temperature fall of hot fluid ÷ temperature rise of cold fluid
ϵ = emissivity of a surface
Γ = mass rate of flow: $w/\pi D$ for vertical; w/L for horizontal tubes
ρ = density, lb per cu ft
σ = 0.1723×10^{-8}, Stefan-Boltzmann constant
θ_1 = temperature difference between hot fluid entering and colder fluid leaving
θ_2 = temperature difference between hot fluid leaving and cold fluid entering
μ = viscosity at bulk temperature, lb per hr per ft = 2.42 times centipoise
μ_s = viscosity of fluid at temperature of the wall

CONDUCTION

Flat Solid Wall. The rate of heat transfer through a flat solid wall of a single material is calculated from the equation

$$= kA \; t_1 - t_2 \tag{1}$$

where k is called the thermal conductivity of the material and is a property of the kind of material and the average temperature of the material. It is the amount of heat transferred per hour through 1 sq ft area of a wall 1 ft thick with a 1°F temperature difference across the wall. Values of thermal conductivity k for various materials are given in the next subsection, Heat-transfer Properties of Materials.

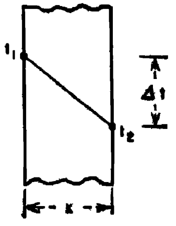

FIG. 27-1. [See Eq. (1).]

Cylindrical Solid Wall. The rate of heat transfer through a cylindrical solid wall of length L is calculated from the equation

$$q = 2\pi Lk \frac{t_1 - t_2}{\ln\ (r_2/r_1)} \tag{2}$$

where r_2 and r_1 are outside and inside radii in feet or inches, ln is logarithm with base e.

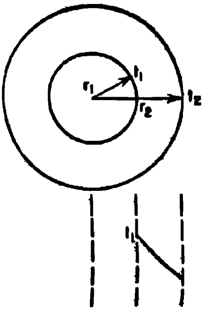

FIG. 27-2. [See Eq. (2).]

Composite Wall. A composite wall is one composed of a number of layers of different materials such as a building wall built up of layers of plaster, stone, and brick or an iron pipe covered with a layer of high-temperature insulation followed by a layer of 85 per cent magnesia. For these walls thermal conductance C of the wall is defined by and the rate of heat transfer is calculated from the following equation:

$$q = CA(t_1 - t_n) \tag{3}$$

where t_1 and t_n are the inner and outer surface temperatures of the composite wall.

For a flat wall composed of $(n - 1)$ layers of material:

$$\frac{1}{(x_A/k_A) + (x_B/k_B) + (x_C/k_C) + } \qquad (4)$$

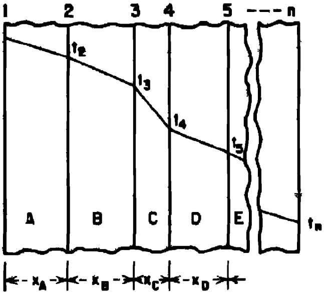

Fig. 27-3. [See Eq. (4).]

where x_A and k_A refer to the material layer A, etc. As many terms appear in the denominator of Eq. (4) as there are layers of different materials.

Cylindrical Composite Wall. For a cylindrical wall composed of $(n - 1)$ layers of material, the product of surface area times thermal conductance is

$$CA = \frac{1}{\dfrac{\ln (r_2/r_1)}{2\pi L k_A} + \dfrac{\ln (r_3/r_2)}{2\pi L k_B} + \cdots} \qquad (5)$$

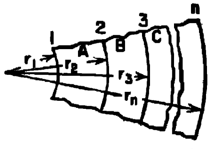

Fig. 27-4. [See Eq. (5).]

The rate of heat transfer q through a flat composite wall is then calculated by substituting the value of C from Eq. (4) in Eq. (3); for a cylindrical composite wall substitute the value of the product CA from Eq. (5) into Eq. (3).

CONVECTION

When a fluid flows parallel to a wall, the thin layer of fluid which is touching the surface clings to the wall and does not move. The fluid just next to this stagnant layer moves in sheets parallel to the wall; this is called the laminar layer. At the outer edges of the laminar layer the fluid in the transition zone tends to break away from its sheetlike formation to enter the turbulent region where it has extremely random motion. Heat transferred between the surface and the main stream must

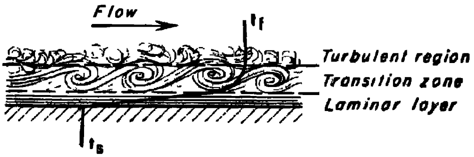

Fig. 27-5. Turbulent flow of a fluid flowing parallel to a surface.

be transferred through these various layers. Heat is transferred by conduction through the laminar layer and by convection through the transition zone. The laminar layer and transition zone combined are known as the film.

Since it is impracticable to separate the effects of these two types of heat transfer in this case, the rate of heat transfer between the surface at temperature t_s and the main body of the fluid at temperature t_f is calculated from the equation

$$q = hA(t_s - t_f) \tag{6}$$

which defines the film coefficient of heat transfer h having the units Btu per hour per deg F temperature difference per square foot of heat-transfer surface. Exact values of this film coefficient are not known in many cases, but empirical equations based on experimental results for the more common cases are given under the heading Film Coefficients, this Section, page 1613.

CONDUCTION AND CONVECTION

An important case of heat transfer is that from a hot fluid on one side of a solid wall to a cooler fluid on the other side. The wall may be a cylindrical or a flat wall of a single material or composite wall of layers of different materials. The rate of heat transfer is calculated from the equation

$$q = UA(t_h - t_c) \tag{7}$$

where t_h and t_c are the temperatures of the hot and the cold fluids, respectively.

Flat Composite Wall. Equation (7) is used to calculate the rate of heat transfer from a hot fluid successively through the hot-side film, layers of solid material of the wall, and the cold-side film to the cold fluid. For this case U of Eq. (7) is

$$U = \frac{1}{(1/h_h) + (x_A/k_A) + (x_B/k_B) + \cdots + (1/h_c)} \tag{8}$$

where h_h and h_c are the hot- and cold-side film coefficients of heat transfer, and the other terms are as defined in Eq. (4).

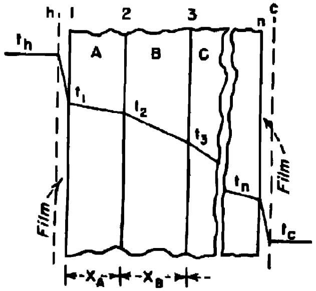

FIG. 27-6. [See Eq. (8).]

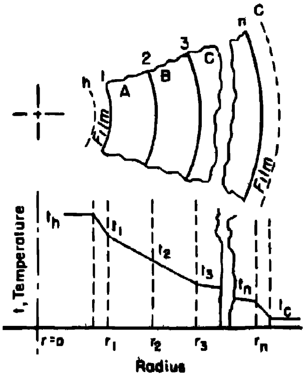

FIG. 27-7. [See Eq. (9).]

Cylindrical Composite Wall. Equation (7) is also used to calculate the rate of heat transfer from a hot to a cold fluid through a composite cylindrical pipe wall. For this case the product UA of Eq. (7) is

$$UA = \frac{1}{\dfrac{1}{2\pi r_1 L h_h} + \dfrac{\ln (r_2/r_1)}{2\pi L k_A} + \dfrac{\ln (r_3/r_2)}{2\pi L k_B} + \cdots + \dfrac{1}{2\pi r_n L h_c}} \tag{9}$$

Surface Temperature. Sometimes it is necessary to know the temperature of the inner and outer faces of the wall and also the temperature at the interface between layers of different materials within the wall. When these temperatures cannot be measured conveniently, they may be estimated by calculation. Consider the flat composite wall shown in Fig. 27-6. The rate of heat transfer q through the wall is calculated from Eq. (7) and (8). In the case of steady-state heat transfer the rates of heat transfer through the films and through each layer of material of the wall are all equal and given by this value of q. The rate of heat transfer through the films is given by Eq. (6) and through each layer of the composite wall by Eq. (1). The temperature of the hot and cold fluids may be measured; and values of film coefficients h_h and h_c may be found under the heading Film Coefficients, this section, page 1613. Thermal conductivity k_A and k_B may be found in Sec. 27, Heat-transfer Properties of Materials, page 1618. Then the surface temperatures t_1 and t_n may be calculated from Eq. (6).

$$t_h - t_1 = q/h_hA$$
$$t_n - t_c = q/h_cA$$

and the interface temperatures may be calculated by successively using Eq. (1). Since t_1 is now known, calculate t_2 from

$$t_1 - t_2 = (qx_A)/k_AA$$

Since t_2 is now known, calculate t_3 from

$$t_2 - t_3 = (qx_B)/k_BA$$

This process may be continued until all interface temperatures are known.

RADIATION

The net rate of heat transferred by radiation from one surface to another separated by a vacuum or a gas which is transparent to the radiation is calculated from the equation

$$q = A_1\mathfrak{F}_{12}\sigma(T_1^4 - T_2^4) \tag{10}$$

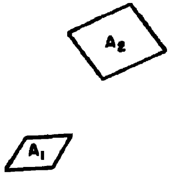

FIG 27-8. [See Eq. (10).]

where A_1 is the area of surface 1. The factor $\mathfrak{F}_{12}$ is calculated from the equation

$$\mathfrak{F}_{12} = \frac{1}{\dfrac{1}{F_{12}} + \left(\dfrac{1}{\epsilon_1} - 1\right) + \dfrac{A_1}{A_2}\left(\dfrac{1}{\epsilon_2} - 1\right)} \tag{11}$$

where ϵ_1 and ϵ_2 are emissivities of the two surfaces, and A_1 and A_2 are areas of the two surfaces. The emissivity ϵ of a surface depends upon the character of the surface and temperature of the surface. Values of emissivity for various surfaces are tabulated in the next subsection, Heat-transfer Properties of Materials. The angle factor F_{12} depends upon the size, shape, and arrangement of the two surfaces exchanging heat by radiation. The value of F_{12} is not known for all surface arrangements and shapes. It has been evaluated for only a few of the more common ones.

Angle Factor, F_{12}. Surfaces for which $F_{12} = 1.00$:

1. A small flat surface radiating to a wall which forms a large hemisphere
2. Concentric spheres or long concentric cylinders such as long pipes

3. Large, closely spaced rectangular or circular plates, where ratio of side or diameter to distance between planes is large (greater than 15)

Surfaces for which $F_{12} \neq 1.00$:

1. Figure 27-9 is for perpendicular rectangular planes.

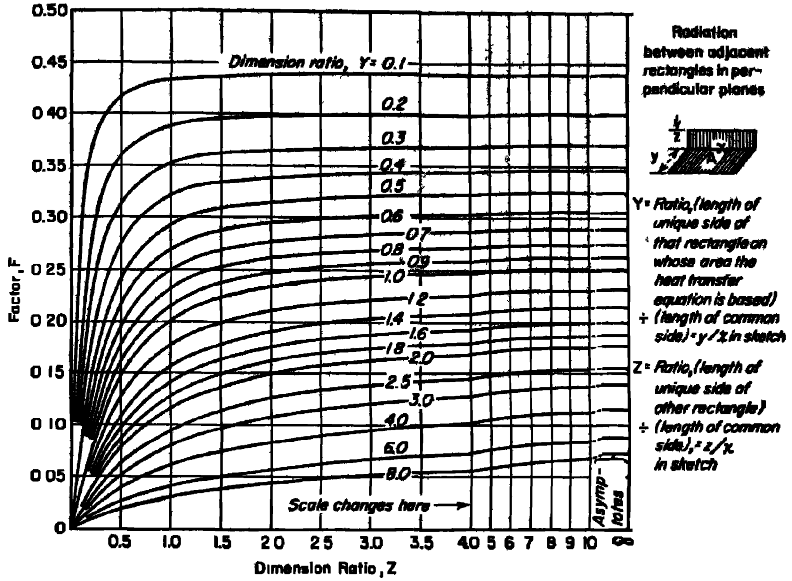

FIG. 27-9.

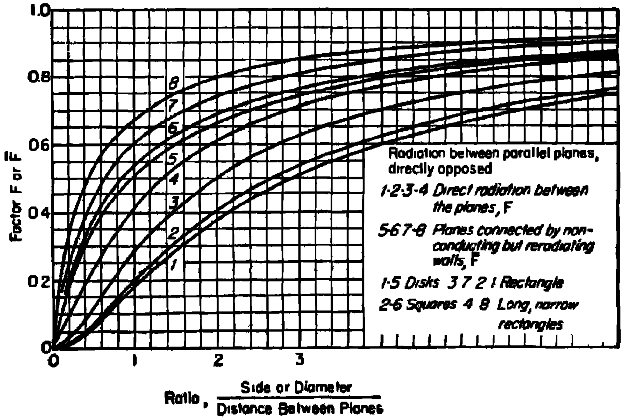

FIG. 27-10.

2. Figure 27-10 shows the angle factor for parallel planes (disks, squares, and rectangles) directly opposite each other. Lines 5, 6, 7, 8 are for planes separated by refractory (nonconducting but reradiating) walls.

3. Figure 27-11 is for radiation between a plane and one or two rows of tubes parallel to the plane.

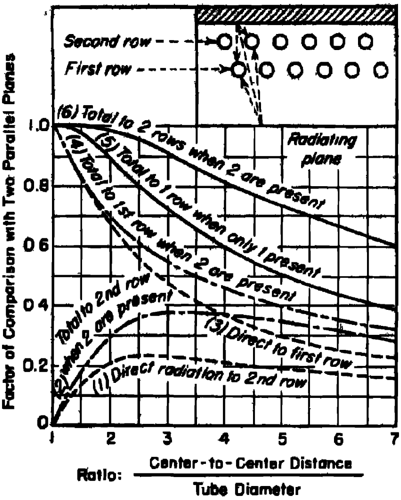

FIG. 27-11.

Problems of furnace design involve radiation of gases, flames, and clouds. A detailed study of these problems is found in McAdams.[1]

CONVECTION AND RADIATION

Heat transfer by convection and radiation occur at the same time from a given surface. Usually one has the greater effect, and the other may be neglected. In some cases, as in heat transfer from bare and insulated pipes, the convection and radiation are of the same order of magnitude. Then it is convenient to use a combined convection and radiation coefficient $(h_v + h_r)$. The rate of heat transfer becomes

$$q = (h_v + h_r)A(t_s - t_f) \tag{12}$$

where h_v is defined by Eq. (6) and is determined from experimental data given under the heading Film Coefficient, and h_r is determined by q_r calculated from Eqs. (10) and (11) from

$$h_r \quad A(t_s - t_f) \tag{13}$$

where t_s and t_f are temperatures of the surface and surrounding fluid, respectively.

For certain special cases, values of the combined coefficient $(h_v + h_r)$ are given also under Film Coefficients.

HEAT EXCHANGERS

The equation for calculating the rate of heat transfer in a heat exchanger is

$$YUA \frac{\theta_1 - \theta_2}{\ln (\theta_1/\theta_2)} \tag{14}$$

This equation assumes constant U, constant specific heats of the two fluids, constant rates of flow, no changes in phase, and negligible heat loss to the atmosphere. The product UA is evaluated as in Eqs. (8) or (9)

Factor Y: For a pure counterflow heat exchanger, $Y = 1$. For various multipass and crossflow heat exchangers, Y is determined from Figs. 27-12 and 27-13.

Steam Condenser. In a steam condenser one fluid is a condensing vapor, and the other is a liquid that does not change phase. The rate of heat transfer is calculated from

$$q = UA \frac{t_{w_2} - t_{w_1}}{\ln [(t_s - t_{w_1})/(t_s - t_{w_2})]} \tag{15a}$$

For condenser tubes with cooling water inside the tubes, the value for UA in the above equation is

$$UA = \frac{N}{\dfrac{1}{2\pi r_1 L h_c} + \dfrac{1}{2\pi r_1 L h_s} + \dfrac{\ln (r_2/r_1)}{2\pi L k_a} + \dfrac{1}{2\pi r_2 L h_h}} \tag{15b}$$

where h_s is the coefficient of heat transfer for the scale deposit in the tubes.

A valuable graphical method of interpreting the results of tests on surface condensers, proposed by E. E. Wilson,[2] consists in plotting $(1/AU)$ vs. $(1/V)^{0.8}$ and drawing the best straight line. When the condenser tubes are cleaned of scale deposit, the value of $1/AU$ at $1/V^{0.8} = 0$ is the sum of the heat-transfer resistance of the condensing vapor and the tube wall. For later tests, when scale deposit has formed, the straight line will be higher on the curve sheet. The difference between $1/AU$ for the "clean" and the "dirty" condition at $1/V^{0.8} = 0$ measures the amount of scale formed and may be used as an indicator for the necessity of cleaning the condenser tubes.

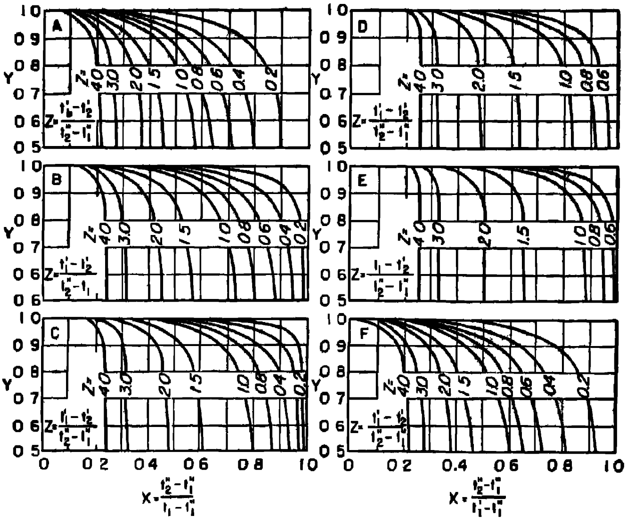

FIG 27-12. Factor Y in reversed-current heat exchangers (shell side well mixed at a given cross section). (A) 1 shell pass and 2, 4, 6, etc , tube passes, (B) 2 shell passes and 4, 8, 12, etc , tube passes, (C) 3 shell passes, and 6, 12, 18, etc , tube passes, (D) 4 shell passes, and 8, 16, 24, etc , tube passes; (E) 6 shell passes, and 12, 24, 36, etc , tube passes; (F) 1 shell pass, and 3, 6, 9, etc., tube passes. [See McAdams (1), page 146.]

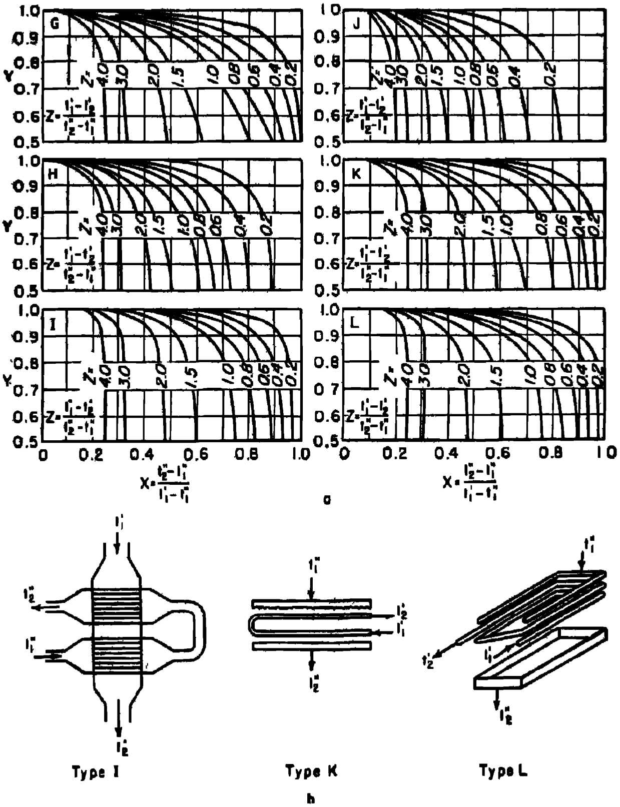
FILM COEFFICIENTS

The value of the film coefficients depends upon two kinds of properties—physical properties of the materials, such as thermal conductivity, viscosity, specific heat, and density, and geometrical properties, such as shape and arrangement of heating surface and velocity of flow across the surface. The problem of prediction of film coefficients divides itself into three velocity ranges. In the high-velocity range *turbulent flow* exists as described in Fig. 27-5. As the velocity is decreased, the laminar layer increases until the entire tube stream flows in a laminar flow. A further reduction in velocity to near zero causes *natural convection* currents to govern the prediction of film coefficients.



a

b

Fig. 27-13. Factor Y in cross-flow heat exchangers: (G) cross flow, both fluids unmixed, 1 tube pass; (H) cross flow, shell fluid mixed, 1 tube pass; (I) cross flow, shell fluid mixed, 2 tube passes—shell flow flows across second and first passes in series; (J) cross flow, shell fluid mixed, 2 tube passes—shell fluid flows over first and second passes in series; (K) cross flow, (drip type), 2 horizontal passes with U-bend connection (trombone type); (L) cross flow, (drip type), helical coils with 2 turns. [See McAdams (1), page 147.]

Turbulent Flow. Most applications met in practice are forced flow of gases or liquids in turbulent flow. An empirical equation correlating the heating of gases and liquids inside horizontal pipes when Re > 4,000 is

$$\mathrm{Nu} = 0.023(\mathrm{Re})^{0.8}(\mathrm{Pr})^{0.4} \qquad (16)$$

where the dimensionless numbers are

Nu = Nusselt number = hD/k
Re = Reynolds number = DG/μ
Pr = Prandtl number = $c_p\mu/k$

The following simplified equations for specific cases are deduced from Eq. (16):

Turbulent flow of gases inside clean straight tubes:

$$h = 0.024[c_pG^{0.8}/(D')^{0.2}] \tag{16a}$$

Turbulent flow of water inside clean straight tubes:

$$h = 160(1 + 0.012t)[V^{0.8}/(D')^{0.2}] \tag{16b}$$

Turbulent flow in coiled pipes:
Multiply h for straight pipes by the factor

$$1 + 3.5(D/D_c)$$

Turbulent gas flow normal to a bank of staggered tubes:

$$DG/\mu > 1{,}000$$
$$h = 0.36[c_pG^{0.6}/(D')^{0.4}] \tag{16c}$$

Turbulent water flow normal to a bank of staggered tubes:

$$h = 370(1 + 0.0067t_f)[V^{0.6}/(D')^{0.4}] \tag{16d}$$

For tubes in line use 75 per cent of the value of h determined from Eqs. (16*c*) and (16*d*); for baffled exchanger use 60 per cent of the values above for unbaffled exchangers.

Streamline Flow. Streamline flow is encountered in the flow of viscous liquids, such as oils, at values of $DG/\mu < 2{,}100$.

The coefficient of heat transfer is calculated from the equation

$$hD/k = 2.0(wc_p/kL)^{1/3}(\mu/\mu_s)^{0.14} \tag{17}$$

Natural Convection. Coefficients of heat transfer by natural convection from surfaces to air are given by the following equations where Δt is the temperature difference between the surface and the surrounding air:

Horizontal plates facing upward:

$$h = 0.38(\Delta t)^{0.25} \tag{18a}$$

Horizontal plates facing downward:

$$h = 0.2(\Delta t)^{0.25} \tag{18b}$$

Vertical plates more than 1 ft high:

$$h = 0.27(\Delta t)^{0.25} \tag{18c}$$

Vertical plates less than 1 ft high:

$$h = 0.28(\Delta t/b)^{0.25} \tag{18d}$$

Vertical pipe more than 1 ft high and horizontal pipe:

$$h = 0.27(\Delta t/D)^{0.25} \tag{18e}$$

Condensing Vapors. When a pure vapor condenses on a tube, the condensate wets the tube resulting in "film-type" condensation. If the condensate flows in streamline motion ($4\Gamma/\mu < 2{,}100$), the following equations may be used:

Horizontal tubes:

$$h = 0.76(k^3\rho^2g/\mu_f\Gamma)^{1/3} \tag{19a}$$

Vertical tubes:

$$h = 0.93(k^3\rho^2g/\mu_f\Gamma)^{1/3} \tag{19b}$$

These values are for pure vapors. If noncondensable gases such as air are present, the values are lower than those calculated from Eqs. (19*a*) and (19*b*). Hence it is essential to vent vapor-heated apparatus.

When steam is condensing the addition of small traces of oleic acid or benzyl mercaptan prevents the formation of a film of the condensate on the surface and induces a "dropwise" condensation resulting in h values that are three to four times larger than those of "film-type" condensation.

Boiling Liquids. Liquids are usually evaporated by natural convection heat transfer from the surface of submerged tubes which are heated internally either by condensing vapors or by electricity. The coefficient of heat transfer depends upon the kind of liquid boiling, the temperature difference between the surface and boiling liquid (Δt), temperature of the boiling liquid, character and arrangement of heating surface, and agitation of boiling liquid. When a liquid is being evaporated at a given pressure, the coefficient of heat transfer rises to a maximum value as the temperature difference between heating surface and boiling liquid is increased; beyond this critical temperature difference its value decreases. This effect for boiling water is shown in Fig. 27-14. It is noted that the critical temperature difference is about 40°F for water boiling at atmospheric pressure.

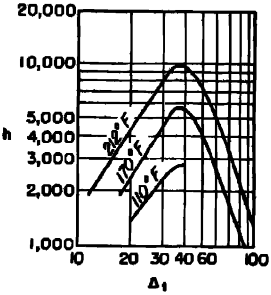


FIG. 27-14. Effect of Δt and t on h for boiling water.

Since $q/A = h(\Delta t)$, the maximum q/A occurs at a Δt greater than 40°F; for boiling water it occurs at about 45°F. If an electric heating element is used, it is essential that Δt be less than the critical value to prevent burning out the heating element or throwing the circuit breaker.

Combined Convection and Radiation. Values of $(h_v + h_r)$ given by Bailey and Lyell[4] for horizontal bare steel pipe in a room at 80°F are given in Table 27-1.

Table 27-1. Values of $(h_v + h_r)$
(For horizontal bare standard steel pipe in a room at 80°F)

Nominal pipe diam, in	Temperature difference, deg F, surface to room							
	50	100	200	300	400	500	600	700
1	2.26	2.50	3.00	3.60	4.34	5.16	6.05	6.98
3	2.05	2.25	2.73	3.31	4.03	4.85	5.71	6.66
5	1.95	2.15	2.61	3.20	3.90			
10	1.87	2.07	2.54	3.12	3.84			

For rotating cylinders in air Hinlein gives values as in Table 27-2.

Table 27-2. Values of $(h_v + h_r)$
(For rotating cylinders in air)

Surface	Velocity, V, fps					
	0	20	40	60	80	100
Smooth polished copper	0.47	1.97	2.79	3.14	3.30	3.38
Rough, dull, black-varnished	0.47	2.49	3.32	3.96	4.50	5.10

For flat surfaces contacting air, Lichty (*Univ. Illinois Bull.*, 1915) gives values as in Table 27-3.

For external surfaces multiply ($h_v + h_r$) by factors shown in Table 27-4.

Table 27-3

Surface in still air	$h_v + h_r$
Cement plaster finish	0.9
Concrete or corkboard	1.3

HEAT-TRANSFER PROPERTIES OF MATERIALS

BY LUCIEN R. VIANEY, B.S.

Assistant Professor of Mechanical Engineering, Massachusetts Institute of Technology

THERMAL CONDUCTIVITY

Before an engineer attempts to use tabulated data on heat-transfer properties, he must realize that "test" data and actual values in the field may vary to a great extent owing to changes within the material being used. The conditions of test and actual use must be compared and proper judgment used in selecting actual values of the various coefficients.

Conductivity k may vary with each of the following items (see Table 27-6).

Mean Temperature.

$$\text{Mean temp} = (t \text{ hot side} + t \text{ cold side})/2$$

The conductivity k of noncrystalline materials will increase with an increase of mean temperature (Fig. 27-15), while crystalline materials will show decreasing k within a certain temperature range, then reversing the curve and increasing conductivity k as temperature increases.

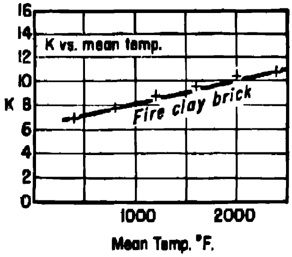

FIG. 27-15. Conductivity vs. mean temperature.

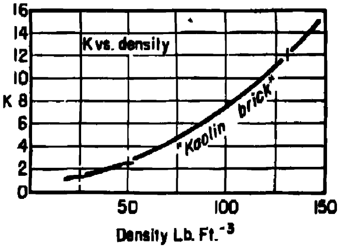

FIG. 27-16. Conductivity vs. density.

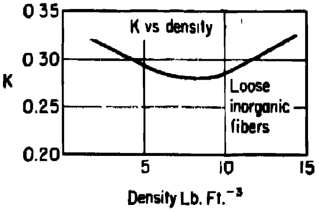

FIG. 27-17. Conductivity vs. density of loose inorganic fibers.

Density (lb-ft^{-3}). If the heat transfer through a given material is by conduction alone, the thermal conductivity will increase with increasing density (Fig. 27-16).

In loose fibrous materials where internal radiation and/or convection may occur, the apparent k may increase with lower densities as may be seen in Fig. 27-17.

Moisture. Not only will k increase with moisture content of the material, but also the heat-transfer coefficients will vary an undeterminable amount owing to moisture vapor migration through the specimen (see Fig. 27-18).

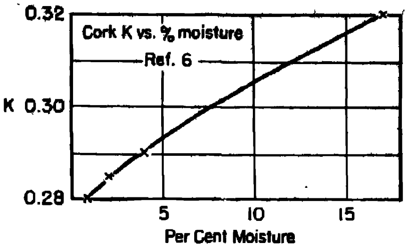

FIG. 27-18. Conductivity of cork vs. per cent moisture.

Pore Size. The conductivity of a material will decrease with a reduction of the size of closed pores; the limits of this reduction are not exactly known however. Experimental plastics with large closed pores and very low density have been found to have much higher k than the same material in a much smaller pore higher density form.

Mixture of Materials. The *k* of a material is not always proportional to the ratio of its components. A single example is given here, but each case would have to be worked out independently (Fig. 27-19)

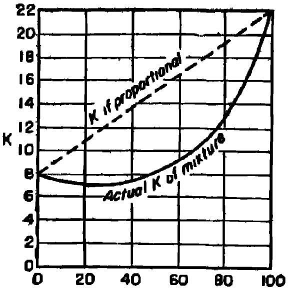

Fig. 27-19. Effect of mixtures of materials on conductivity.

EMISSIVITY

Total emissivity ε, the second property, which is shown in Table 27-7, is in general very difficult if not impossible to estimate by visual inspection of the surface This quality of a material may vary with the following items.

Nature of Surface. In general, bright clean metal surfaces will have low emissivity (0.03 to 0.10) at moderate temperatures, while nonmetallic materials, such as wood, paper, cloth, paints, etc, will have high emissivity (0.75 to 0.95) at the same temperature range

Surface Treatment. The mechanical treatment or condition of a surface is vital to its reflective properties. Polishing will decrease the ε of a surface, while any sort of roughening will increase emissivity.

Chemical treatment or painting a surface even with an extremely thin translucent coating may greatly increase the emissivity of a metal surface at moderate temperature ε values of treated surfaces are probably uncertain by 10 to 30 per cent.

Temperature. The emissivity ε of a surface is a function of the wavelength of the radiation being absorbed or reflected by the surface The wavelength of the radiation being absorbed or reflected is a function of temperature Therefore all data on emissivity should state the range of temperature at which the material was tested. For example, white paint is a poor reflector of low-temperature radiation but a good reflector of solar radiation

PHYSICS IN THE INDUSTRIES

BY LYMAN M. DAWES

Assistant Professor of Industrial Applications, Emeritus and Honorary Lecturer, Department of Electrical Engineering, Massachusetts Institute of Technology

X-RAYS

The discovery of X-rays dates from Nov. 8, 1895, when William Conrad Roentgen, while experimenting with cathode rays (streams of guided electrons), discovered that their impact on the walls of the tube to which they were confined produced a phenomenon, previously unknown, which because of its unknown character he called X-rays.

The general properties of X-rays were rather completely stated by Roentgen after he had experimented but a few weeks. In essence they were as follows: Many substances fluoresce when exposed to the rays; sensitized photographic materials respond to their action; they cannot be reflected or refracted by lenses; they travel in straight lines and are not deflected by magnetic fields; they discharge electrified bodies, whether the bodies are electrified positively or negatively; they are generated when cathode rays strike any solid body, and the heavier the element struck, the more efficient the generation of the X-rays.

Table 28-1. Wave Lengths and Frequency in the Electromagnetic Spectrum

Type of radiation	Wave length, cm	Frequency, cps	Some uses
Gamma rays caused by cosmic rays	Shorter than gamma rays from radioactivity	Higher than gamma rays from radioactivity	Scientific experimentation
Gamma rays	1.4×10^{-8}–2×10^{-11}	2.1×10^{18}–1.5×10^{21}	Radiography, therapeutics
X-rays	10^{-6}–6×10^{-10}	3×10^{16}–5×10^{19}	Radiography, fluoroscopy, therapeutics
Ultraviolet rays	4×10^{-5}–1.4×10^{-6}	7.5×10^{14}–2.1×10^{16}	Photography, phosphorescence, fluorescence, therapeutics, chemical changes, ionization of gases, photoelectric effects, sterilization
Visible rays	3.9×10^{-5}–7.7×10^{-5}	3.9×10–$^{14}7.7 \times 10^{14}$	Seeing, photography, photoelectric, and photochemical effects
Infrared rays	7.7×10^{-5}–4×10^{-2}	3.9×10^{14}–7.5×10^{11}	Heating, specialized photography, therapeutics
Short Hertzian waves	1×10^{-2}–1×10^{3}	3×10^{12}–3×10^{7}	
Radar	3×1–3×10	10^{10}–10^{9}

Ordinary telegraph	....	10– 25	
Power work	....	25– 800	

The new discovery was immediately put to use in the medical and physical sciences, and other physicists discovered that X-rays can be polarized; are reflected from a smooth surface if they strike the surface within a fraction of a degree of parallelism; are slightly diffracted on passing through a narrow slit; are bent by refraction in passing through a substance; will either stimulate or destroy living tissue, depending upon the exposure; are scattered by the atoms of a substance, and when the substance is crystalline exhibit a pattern that identifies or establishes the substance's crystalline arrangement; can expel electrons from a substance, in which case the electrons expelled produce fluorescent rays; and the rays have been found to possess definite momentum and energy or quanta.

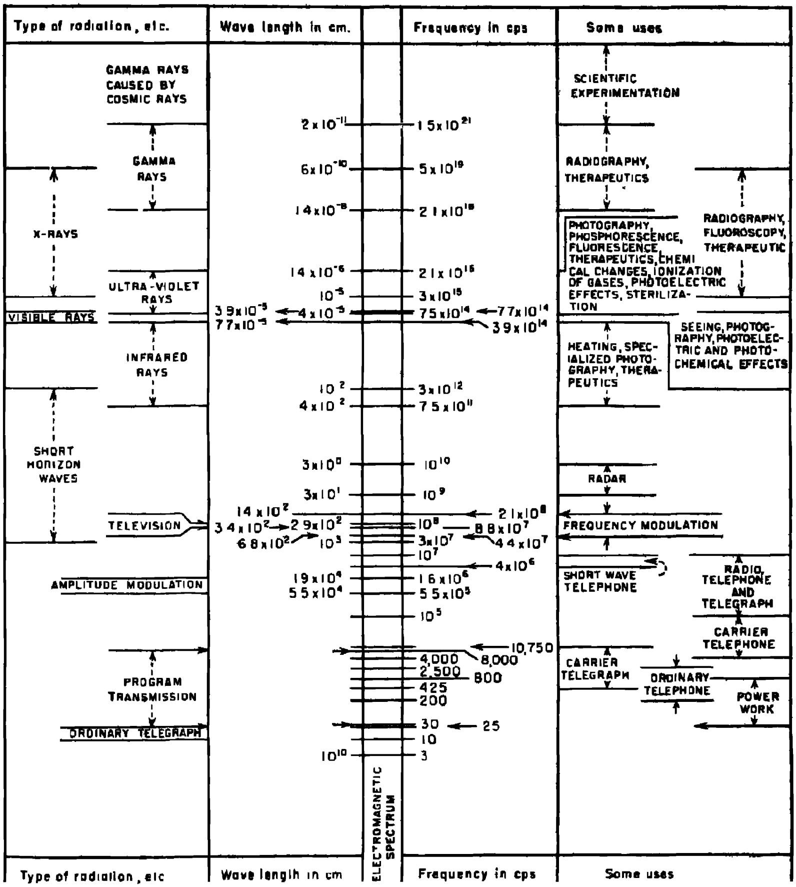

FIG. 28-1. Diagram of electromagnetic spectrum. A straightedge laid across the diagram will enable the user to identify the wave length and frequency bands by "Type of radiation" and "Some uses."

Electromagnetic waves as indicated in Table 28-1 and Fig. 28-1, include X-rays and gamma rays, closely associated radiations of very high frequency. Gamma rays are emitted during the radioactive disintegration of the heavier elements. It is now thought that they also result when cosmic particles impinge on matter. The impinging cosmic particles move under the influence of voltages more than a thousand times the high voltages used in the production of X-rays. The voltages for the production of X-rays range from a few thousands to a few millions of volts at present. As the voltage impelling a stream of electrons or cathode rays is increased, the velocity of the electrons is increased, and X-rays of shorter wave lengths are emitted on the impact of the electrons as their energy is increased.

The phenomena of electromagnetic waves are related by the equation

$$v = C/\mu\epsilon \tag{1}$$

where v = velocity of the wave train
C = ratio of electrostatic to electromagnetic charges
μ = permeability
ϵ = dielectric constant of the medium in which the waves are propagated.

These phenomena are also related by the equation

$$C = \lambda f \tag{2}$$

where C = velocity of light, usually taken as 3.0×10^{10} cm per sec [2.99796×10^{10} cm per sec (Michelson, 1926)]
λ = wave length of the radiation, cm
f = frequency, cps.

Within experimental error, C in Eq. (1) is equal to C in Eq. (2). In other words the velocity of light in empty space ($\mu = 1$, $\epsilon = 1$) is equal to the ratio C between the electrostatic and electromagnetic systems of units. Also

$$\lambda = hC/Ve = 12{,}350/V \quad \text{cm } 10^{-8} \text{ (minimum length)} \qquad f = Ve/h$$

where e = charge on the electron, esu
V = voltage between the electrodes of the tube
h = Planck's constant, equal to 6.55×10^{-27} erg-sec

The production of X-rays by the impact of the cathode rays on matter is associated with the phenomenon of photoelectric emission, and the kinetic energy of the photoelectrons is equated to light quanta and frequency by Einstein's photoelectric equation,

$$\tfrac{1}{2}mv^2 = hf - \omega_0$$

where m mass
v = velocity of the photoelectron
ω_0 = work required for the photoelectron to escape from the emitter.

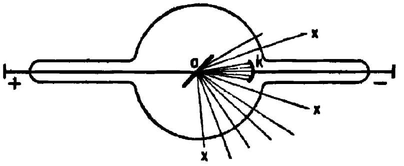

FIG. 28-1*a*. Early X-ray tube.

The generation of X-rays was at first produced in tubes such as that represented diagrammatically in Fig. 28-1*a*. It consisted of a spherical bulb tubulated at opposite ends of its diameter. Within the bulb was located a concave mirror of metal, usually aluminum, which served to bring the cathode rays to a focus on the anode placed near the center of the tube. The anode was made of a plate of platinum. Lead-in wires + and − extended to the anode and cathode respectively. When the terminals were connected, as marked in the figure, to a source of sufficiently high potential, X-rays were emitted from the surface of the platinum anode in all directions as indicated by x. In order that this tube may generate X-rays, it is necessary that it be filled with a gas at a low pressure (0.001 to 0.01 mm Hg). Under this condition and with a sufficient voltage on the electrodes, the gas becomes ionized, and a stream of electrons moves from the cathode to the anode as cathode rays. As the tube is used the pressure drops and ionization fails. To maintain this pressure relatively constant, many clever devices have been contrived. One scheme is shown in Fig. 28-2.

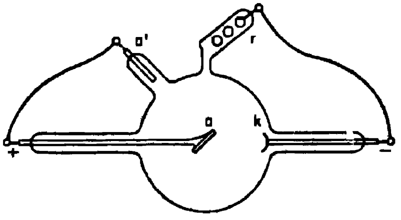

FIG. 28-2. Constant-pressure X-ray tube.

Material containing considerable adsorbed air, *e.g.*, mica, is introduced into an auxiliary tube r connected to the main chamber. When the pressure of the gas in the main bulb is lowered by the absorption of part of the gas, the resistance of the tube to the passage of the electric current is increased. When the resistance rises sufficiently, the current will be by-passed over the path from a′ to r. This results in heating of the gas-holding material, and gas is released to enter the main chamber. This corrects its partially exhausted condition, enabling it to continue to function. Tubes of this early type are still in use to a limited extent. It was the only type of X-ray tube in use until Dr. W. D. Coolidge developed the high-vacuum tube in 1913.

The high-vacuum or Coolidge tube is indicated diagrammatically in Fig. 28-3. In this tube the highest attainable vacuum is produced. The electrons are supplied by emission from the hot filament *f* which is at the same potential as the cathode *K*. The anode is often of copper with a tungsten plate inserted, thus providing a rugged target of high efficiency combining high melting point, high atomic number, and low vapor pressure. The copper has high thermal conductivity to facilitate heat transfer. The cathode stream is produced by evaporation of electrons from the hot filament of pure tungsten, and the high velocity of the particles in the stream is produced by the high voltage between the cathode and anode. The intensity and penetrating power of the X-rays may therefore be independently adjusted. The temperature of the filament, hence its emission, is adjusted by changing the voltage supplied by battery *B* or its equivalent, and the voltage applied to the electrodes is controlled by means of the generator.

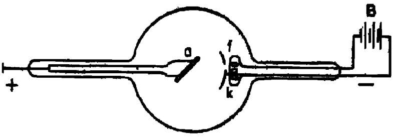

Fig. 28-3. High-vacuum or Coolidge X-ray tube.

Modern X-ray tubes are not so simple nor so uniform in construction as the foregoing paragraphs might imply. There are many problems in tube construction that years of development have not completely solved. Still the modern X-ray tubes are models of ingenuity and marvels of performance. They assume numerous forms and varied details in their construction, so that they may meet innumerable demands as to usage, precision, and economical life. Many of the required design features center about the focusing of the cathode rays to secure a suitable focal spot for the distribution of the X-rays without overheating the target or otherwise spoiling the tube. For many purposes an intense beam of X-rays, radiated from a focal spot of a few square millimeters, practically approximating a point source, is desirable. This condition is needed in radiography and fluoroscopy, where as close an approximation to a point source of X-rays as possible is desirable. For other purposes a focal spot several hundred square millimeters in area, the size of a dime or nickel, is warranted. This use would be in X-ray therapy, *e.g.*, in irradiation of tumors. Much of the difficulty stems from the fact that generally less than 1 per cent of the energy in the tube is converted into X-rays. For example, if a 100-kv tube (a medium-voltage tube) operates at a current of but 10 ma, the target receives 1,000 watts of power. A target of a few ounces receiving energy at such a rate will become white hot in a fraction of a minute unless some means of cooling it is provided.

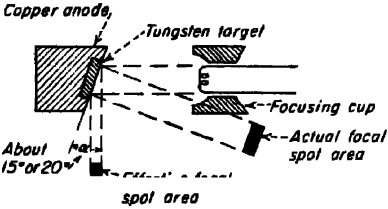

Fig. 28-4. Benson focus for X-ray tube.

The heating of tubes is controlled by many devices tending to limit, distribute, or dissipate the energy concentrated in the relatively small target. The destruction of the target may result from its melting or being so severely pitted that it can distribute only a small portion of the rays formed. The limitation of the heat is illustrated in the so-called universal tube, which has a target of solid tungsten and operates at an energy level below that at which the massive tungsten target will radiate. The target therefore operates at incandescence, and the tube is limited to an input which will prevent the tungsten from attaining a damaging temperature. But at this high temperature the tungsten emits electrons, and the tube is not self-rectifying and must be used on a d-c source. This tube may be used at a low intensity over long periods of time or at higher intensities for shorter periods of time. The ordinary universal X-ray tube may be used at 100 to 150 kv and 5 or 10 ma. Tubes similar to this, but with a specially constructed shield over the anode, having a rating about five or six times as great, are for use at 200 kv and a current of 25 or 30 ma.

One method of increasing the effective intensity of the X-rays from a tube while maintaining a lower intensity of electrons on the target is to focus the beam of electrons into a rectangular band and emit them in the form of a square having a side equal to the band width. This scheme is indicated in Fig. 28-4. The actual area of the electron beam striking the target is as indicated on the target as focal-spot area, but the resultant X-ray beam is about three times as intense as the normal beam would be when it leaves the target at the angle α instead of normally. This device is known as the Benson focus.

In addition to using the Benson focus, the tungsten electrode is frequently made in the form of a truncated cone with sides at an angle of 15 or 20 deg to its base. This target is mounted on one end of a shaft that has the rotor of an induction motor mounted on the other end. This assembly, together with a suitable bearing, is mounted within the tube. A stator is mounted outside the tube concentric with the rotor. A means is thus provided for rotating the target so that the focal spot is continuously moving over its surface. In this manner a much greater loading of the tube is possible with improved radiographic quality because of the higher intensity X-ray beam. The arrangement is indicated diagrammatically in Fig. 28-5. Many useful developments of rotating anode are included in the X-ray tubes of many manufacturers. To provide mechanical strength, tubes are made of Pyrex, or other heat-resisting glass, varying in thickness from the neighborhood of ⅛ to ¼ in. or more. Some tubes are made double walled.

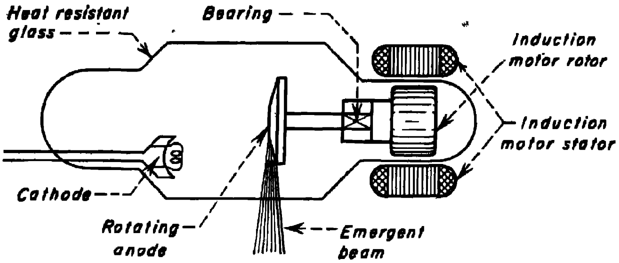

FIG. 28-5. Rotating anode for X-ray tube.

Cooling of X-ray tubes becomes more and more difficult as their capacity increases. A heavy copper support for the target can conduct considerable quantities of waste energy to the outside of the tube. A radiator is often placed on the outside end of the support to facilitate the dissipation of this heat. As the capacity of the tube is further increased, air may be blown across the radiator or liquid cooling embodied in the construction of the tube. The copper anode is often made hollow and oil or water circulated within it close to the target so that heat is carried rapidly to the outside of the tube. Water is about six times as effective as oil in carrying away the heat but presents electrical problems in its use not inherent in the oil.

Tubes are often completely immersed in a specially prepared mineral oil in an enclosing container. This permits connection by high-voltage cables to totally enclosed terminals and results in the "shockproof" tube for the greater protection of operating personnel.

Many other problems—thermal, electrical, and mechanical—are encountered in the making of modern X-ray tubes. With capacities hundreds of times as great as those of the early gas tubes, great quantities of heat must be dissipated. Voltages in the millions require the division of the tubes into numerous stages, each energized by the fraction of the total voltage that will meet the insulation problem and prevent flashover. Stray electrons must be recovered and drained away. Electrode spacing must be correct for the operating voltage—not close enough to allow cold-cathode emission or far enough to make focusing difficult. The envelope must be sufficiently rigid so that the electrodes may remain aligned even when one is rotating. The envelope must withstand heat without excessive change in shape or in resistivity when it is the insulator between electrodes. The necessary design conditions have been met by experienced and reputable manufacturers, and the tubes that they recommend for particular types of service may be used with confidence.

The voltage demand for X-ray tubes may vary from 5,000 to 50,000 volts for soft X-rays of low penetration, 20,000 to 200,000 volts for medium penetration, and 100,000 to several million volts for hardest rays with the highest penetration. In the early days of X-rays when the very high voltages and intensities were not required, static generators such as the Wimshurst machine were used. Many large induction coils were also used which furnished a pulsating direct current. Present-day practice usually embodies an a-c transformer with a high-voltage secondary, together with some form of rectifier to convert the alternating current to direct current. The rectifier may be a rotating spark gap driven by a synchronous motor which is fed from the primary circuit. The rotation of the commutator shown in Fig. 28-6 is in synchronism with the reversal of the alternating current. The commutator is so connected that, when the alternating current reverses, the connections through the brushes also reverse, thus causing the current to flow in one direction on the d-c side of the device. This contrivance is not suitable for reversal of large currents because at every reversal the brushes short-circuit the gap in the commutator, and severe sparking results.

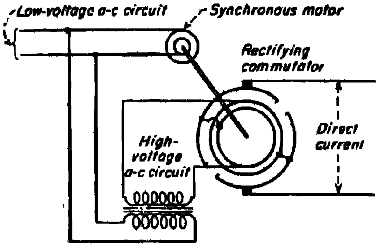

Fig. 28-6. Rotating commutator for voltage rectification.

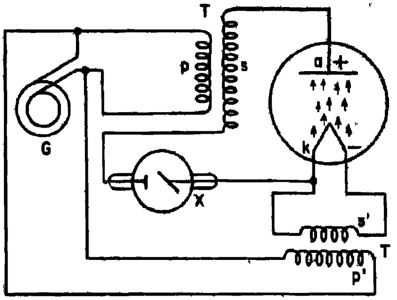

Fig. 28-7. Vacuum-tube rectifier, half-wave.

The vacuum-tube rectifier lends itself most readily to the rectification of high voltages with low currents. Figure 28-7 shows a circuit of a one-tube diode half-wave rectifier. Alternating current of customary commercial frequency is furnished by generator *G* to transformers *T* and *T'*. The low-voltage transformer *T'* has its secondary *S'* connected to the cathode or filament *K* for the sole purpose of heating it to cause the emission of electrons. At one-half cycle the conditions shown exist. Current may then flow by the electrons (negative charges of electricity) from the cathode, as shown by the small arrows, across the interelectrode space to the anode *a*, and through the transformer winding to the cathode of the X-ray tube. The electrons then cross the tube to the anode or target and back to the filament of the diode. During the next half cycle the anode becomes negative and repels the electrons, thus blocking the flow of current. This assumes that the tube will stand the inverse voltage without arcback, *i.e.*, that the inverse voltage rating of the tube should exceed the applied inverse voltage.

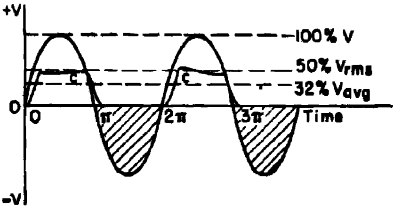

Fig. 28-8. Rectification of an a-c wave, half-wave rectification.

Figure 28-8 indicates an a-c wave assumed sinusoidal. A cycle extends from 0 to 2π and includes all positive and negative values of voltage. When a load is connected to the tube, a current will flow through the load somewhat as shown at *c*, its shape depending on the nature of the load. The negative half cycle, shown cross-hatched, is blocked out or not permitted to flow by the negative anode and positive cathode. The voltage shown as 100 per cent is the voltage across the electrodes of the tube, which is always somewhat less (from a few volts to some hundreds, depending on the characteristics and use of the tube) than the voltage impressed by the transformer. With half-wave rectification the rms voltage is 50 per cent of the net cathode-anode voltage, and the average voltage is 32 per cent of the cathode-anode voltage.

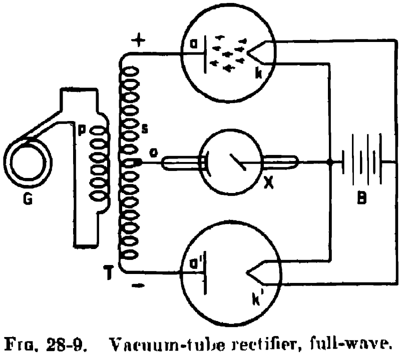

Fig. 28-9. Vacuum-tube rectifier, full-wave.

Full-wave vacuum-tube rectification is shown in Figs. 28-9 and 28-10. In Fig. 28-9 the upper tube is conducting from the cathode *K* to anode *a* through the X-ray tube X back to the cathode, since the anode is positive and the cathode negative. During this period the conditions in the lower tube prevent conduction, since the anode is negative and the cathode positive. During the next half cycle the conditions are reversed, and the upper tube is idle while the lower tube conducts. In this way the rectification of the voltage wave is accomplished, and current flows in only one direction through the X-ray tube *X*. The process is graphically indicated in Fig. 28-10. Two a-c cycles are shown with the negative halves dotted. Current flows always in a positive direction as indicated by the half waves *c*, *c*, *c*, *c*. The rms voltage is greater in full-wave rectification than in half-wave rectification by a factor $\sqrt{2}$; it is 70.7 per cent of the cathode-anode maximum voltage, and its average value is 63.9 per cent of this voltage. The full-wave rectifier is generally more efficient than the half-wave rectifier, depending on the characteristics of the load. It, however, requires exciting current for two cathodes rather than one. The ripple factor is lower in the full-wave rectifier. The ripple factor determines how closely the voltage approaches a direct or constant value. The lower the ripple factor, the more nearly the voltage approaches a constant voltage.

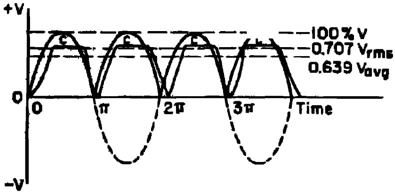

FIG. 28-10. Rectification of an a-c wave, full-wave rectification.

Full-wave bridge-type rectification is shown in Fig. 28-11 where four diodes are connected in a bridge circuit. Tubes *A* and *B* are conducting when the upper terminal of the transformer is positive, and tubes *C* and *D* are conducting during the time that the lower terminal is positive. This arrangement has the same tube efficiency, ripple factor, and percentage output voltage as the center-tap rectifier. However, full use is made of the transformer so that a smaller and more economical transformer may be used. This circuit also subjects the diodes to half the inverse voltage, which may result in economy in tube equipment even though twice as many tubes are required. It may be a disadvantage to have four exciting branches rather than two.

Other forms of rectifiers embody three-phase, six-phase, and other circuit combinations which decrease the ripple factor and provide a closer approximation to a direct current of constant value. It is not generally considered that the additional complication, expense, and lack of flexibility of multiphase circuits are warranted, since the resulting radiograph represents no improvement over those produced by single-phase X-ray generators. The multiphase systems possess the further disadvantage that polyphase supply is not so universally available as single phase is, particularly for portable use.

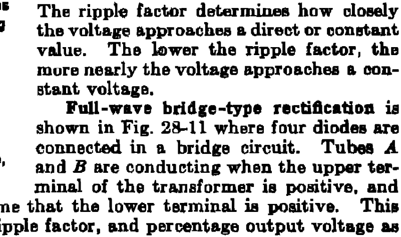

FIG. 28-11. Bridge-type rectification.

Self-rectification may take place in the X-ray tube itself, and this is a simple way of producing X-rays. Current results only by the movement of electrons from the cathode to the anode. In the high-vacuum X-ray tube, electrons are emitted from the filament; and these electrons, or negative charges of electricity, will move from the cathode to the anode whenever the anode is sufficiently positive with respect to the cathode. This occurs on alternate half cycles, as discussed under vacuum-tube rectification by means of diodes, and will occur during all that part of a cycle when the potential is high enough in a positive direction to impel them across the space from cathode to anode. This occurs during the greater part of each alternate half cycle. Thus, an intermittent direct current is provided, and X-rays of an intermittent character are produced by the recurrent positively directed cathode stream during nearly half the time when a high-potential alternating current is applied to the tube. Figure 28-12 is a diagram of the arrangement. The high-potential transformer supplies the voltage to the electrodes, and the low-potential transformer excites the filament. The primary windings of both transformers are connected to any convenient source of commercial electrical power.

The circuit of Fig. 28-12 does not provide for adjustment of voltage on the tube electrodes nor any control for the filament voltage. In most X-ray work such controls are necessary in order that the penetrating power and intensity of the X-ray beam may be adjusted to the requirements of the work. Autotransformers or reactors may be combined with the elements of the circuit shown in Fig. 28-12, as indicated in Fig. 28-13. Connections to the taps in the primary of either one or both transformers may be adjusted to regulate the voltage of the circuit in a manner similar to the method indicated at *AT*. An optional method of voltage adjustment is a variable reactor which may be inserted in the primary circuit of the transformer, as shown at *VR*. In either case the voltage of the primary, and hence the secondary, is adjusted.

A valuable improvement in X-ray practice is the use of the very-high-voltage d-c generators of the Van de Graaff type. These generators are now used with voltages of several million volts and with the X-ray tube built into the generator enclosure The physical size and weight of the equipment are not excessive, and very high efficiencies are attained (as high as 7 per cent at present). The target is made of gold, having a higher atomic number than tungsten, and thus higher X-ray emitting efficiency and ready cooling are attained because of its higher heat conductivity. The direct constant voltage is of great value, as it eliminates the self-rectification and intermittent operation present in the ultra-high-voltage a-c tubes. These elements combine to increase the intensity and penetrating power of the X-rays emitted. The intensity increases in a square-law relationship (doubling the voltage results in four times the intensity), an increase in the voltage causes a decrease in wave length, thus increasing the penetration, and for a fixed voltage the intensity is directly proportional to the tube current. The combination of these features results in very efficient equipment.

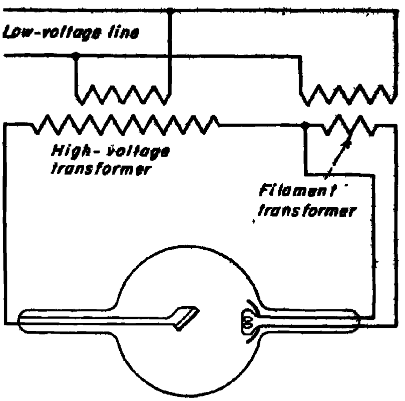

Fig. 28-12. Circuit of self-rectifying X-ray tube.

The elementary characteristics of X-radiation are required knowledge in the rational use of this powerful instrumentality. The essential characteristics of X-rays were summarized on pages 1624–1626. Before X-rays were discovered it was recognized that cathode rays, or high-speed electrons from a beam, when encountering solid matter penetrated it to the depth of a few millimeters. In fact, Roentgen was studying the behavior of these cathode particles when he discovered that in addition to penetrating the surface they caused the emission of a hitherto undiscovered form of electromagnetic radiation which he called X-rays. The place of this radiation in the electromagnetic spectrum has already been shown on page 1624. Quantitative expressions connecting wave length, velocity of light, Planck's constant, voltage, and charge on the electron are given on page 1624.

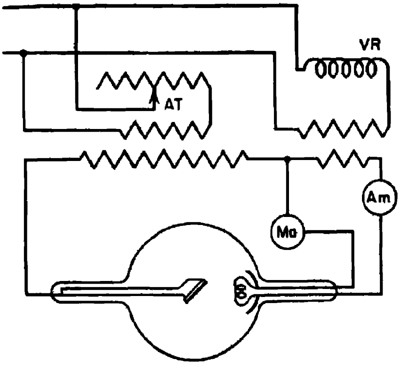

Fig 28-13. Circuit for regulating voltages and X-ray intensities by autotransformer and reactor.

The absorption of X-rays, a measure of what a technician might call "penetrating power," has been determined and tabulated for many substances. When a beam of X-rays encounters matter, it is absorbed in varying amounts dependent upon the coefficient of absorption of the particular material. The relationship is

$$\log I/I_0 = -\mu x$$

where I_0 = intensity of the incident beam
I = intensity of the emergent beam
x = thickness of the tablet of material
μ = coefficient of absorption

The coefficient of absorption may be determined by measuring I, I_0, and x. This proportionality factor has been published for numerous substances. If ρ represents the density of the material, we may introduce it into the foregoing equation to obtain

$$I = I_0 e^{-(\mu/\rho)\rho x}$$

Then ρx is the mass of a section of the tablet 1 cm square and x cm thick measured through the tablet; then the quantity μ/ρ is the mass absorption coefficient, a quantity often used. It is obvious that by making use of this relation, the intensity of the emergent beam of X-rays can be predicted if the intensity of the incident beam is known.

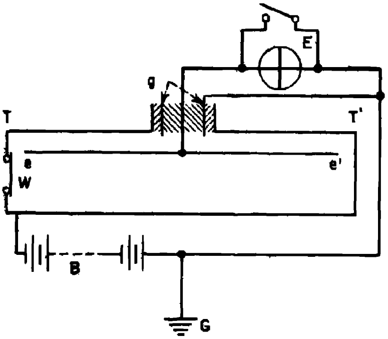

FIG. 28-14. Circuit for X-ray ionization chamber or roentgenometer.

Measurement of the ionization produced by X-rays may be used to determine their intensity, *i.e.*, X-rays ionize gases, or render them conducting, and a quantitative determination of the change in conductivity of the gas gives a measure of the X-ray intensity. It has been found that H, CO, CO_2, air, ether vapor, and CS_2 are increasingly active in the order given in their discharging action, *i.e.*, this activity increases with increase in gas density. The intensity of the beam may be conveniently measured by an ionization chamber arranged as indicated in Fig. 28-14. A metal tube T-T' has an electrode e-e' well insulated from it to prevent leakage from the electrode to the tube. The leakage is furthermore prevented by the grounded guard ring g. An electric field is maintained between the tube T-T' and the electrode e-e' by the battery B. X-rays enter the chamber through the thin aluminum window W, rendering the gas within the tube conducting, thus allowing the charge to move from the tube to the electrode. The rate of movement of the charge is determined by the electrometer E, which is therefore a measure of the rate of ionization and hence of the intensity of X-rays. Commercial instruments are offered for this purpose having the electrometer calibrated in roentgens[1] for a particular ionization chamber. This combination constitutes a roentgenometer and is often supplied with two or more scales on the electrometer calibrated to agree with an equal number of ionization chambers of different roentgen range. The instrument is a practical necessity to determine quantitatively the stray and secondary X-radiation for purposes of protecting personnel from injury.

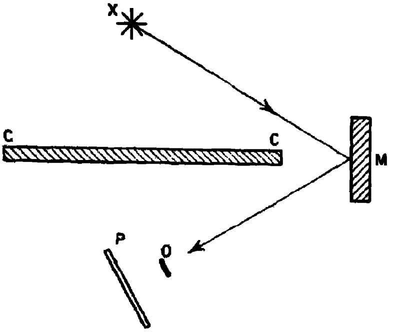

FIG. 28-15. Imbert and Bertin-Sans arrangement of X-ray screen.

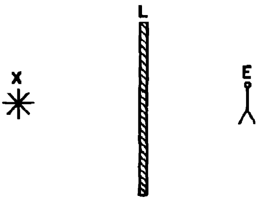

FIG. 28-16. Scattering of X-rays in air shown by discharge of shielded electroscope.

X-rays are scattered or diffused somewhat as light is scattered by fog. Imbert and Bertin-Sans arranged a screen of copper cc, a source of X-rays X, a mirror M, object O, and photographic plate P, as shown in Fig. 28-15. The position of the plane mirror was such that the beam of X-rays, if reflected, would cause a shadow of the object O to appear on the photographic plate P. A shadow was obtained regardless of the angular position of the mirror. It was also observed that a plate of paraffin was just as effective as the mirror. They reached the conclusion that the rays were scattered on striking the paraffin. At about the same time, Righi placed an electroscope behind a lead plate as shown in Fig. 28-16. X-rays from the source X discharged the electroscope E, although it was screened from direct rays. It was later determined that this phenomenon resulted from the scattering of the rays by the air.

---

[1] Roentgen is the international unit of quantity of roentgen rays adopted by the Second International Congress of Radiology at Stockholm in 1928. It is the quantity of X-radiation which, when the secondary electrons are fully utilized and the wall effect of the chamber avoided, produces in 1 cc of atmospheric air at 0°C and 760 mm Hg pressure such a degree of conductivity that one electrostatic unit of charge is measured at saturation current.

The hardness or quality of X-rays is an attribute which determines the penetrating ability of the rays. The shorter the wave length, the harder the rays and the greater their penetrating ability. It may be expressed as the thickness of a given medium (*e.g.*, copper) which will absorb one-half the incident radiation. The quality of the X-rays is a function of the voltage. For a given minimum wave length there is a corresponding peak voltage given by

$$\lambda_0 = 12{,}350/V_0$$

where λ_0 is the minimum wave-length angstroms, and V_0 is the peak voltage in volts (see page 1626).

The medical use of X-rays embraces two main practices: radiography for diagnosis and surgery and therapy for the treatment of certain diseases, particularly some skin diseases and malignant or cancerous growths. For medical radiography, voltages range from 25 to 100 kv for usual work and currents from 5 to 100 ma. (Some special instantaneous radiographs may use 1,000 or more ma.) The optimum voltage and current in a particular case depend on the nature of the tissues as well as the depth that must be penetrated by the X-rays. Voltages beyond 100 kv are of little use in medical radiography. The decreased absorption under excessive voltages reduces contrast and detail in the resulting radiograph. The density of the radiograph is controlled by the intensity of the X-rays. Hence exposures are adjusted by the tube current, often called "milliamperage" by the technician; but the quality of the X-rays, which does not affect the exposure, is dependent on tube voltage which controls X-ray wave length.

A technique often employed to improve the contrast of certain transparent organs in the body is the introduction of diagnostic opaques. A common procedure in radiography of the gastrointestinal tract is to give the patient a suspension of barium sulfate in milk to drink. Other substances opaque to X-rays involve iodine salts, such as sodium iodide for the kidneys, sodium tetraiodophenolphthalein for the gall bladder. Thorium hydroxide and thorium dioxide are introduced. Some substances may be chosen for their selective absorption by the tissue to be radiographed; others may be introduced by injection at the site.

Another diagnostic technique is the photographing on small film, say, 35-mm motion-picture film, of the actinic light emitted by a large fluorescing screen exposed to X-rays. A full-sized chest plate of an adult requires a 14- by 17-in. film. A fluorescent screen may be interposed between a person's chest and a small camera and the film made to record the fluorescing chest plate. The small radiograph is then enlarged 10 or 15 diameters for study. The cost of radiography is thus reduced to a point where it does not militate against routine examinations of factory workers or school children so that tuberculosis or other diseases may be detected in their early stages.

It is very often an advantage to use intensifying screens in radiography. A very small percentage of the rays incident on the photographic emulsion— of the order of 1 per cent—is useful in changing the light-sensitive material. The remainder pass on through the film and are lost or, worse still, are scattered as they strike objects beyond the film—even air. This results in a fogging of the film and consequent obscuring of the image. This condition may be substantially improved by the use of intensifying screens. Several substances, such as barium platinocyanide, cadmium tungstate, calcium tungstate, zinc silicate, or zinc sulfide, have the property of fluorescing under the action of X-rays. A cardboard is coated with one of these fluorescent materials, usually calcium tungstate, to form a screen. In use, a photographic film is placed between two of these screens and the whole loaded in the cassette (film holder for X-ray use) in such a manner that both screens make good contact with every point of both surfaces of the film. When this assembly is exposed to X-rays, the image of the shadow is greatly improved with a reduction in exposure time by a factor of between 10 and 50. The grain size of the fluorescent material affects the exposure time. Large grains allow shorter exposure time with a decrease in detail, while smaller grains improve the detail but increase the time of exposure. Special film known as "screen film" is made for use with intensifying screens. "Nonscreen film" is made for direct use or use with lead screens.

Another method of decreasing the effect of scattering in making radiographs is by use of the Potter-Bucky diaphragm. This device consists of a grid of strips of lead alternating with a material virtually transparent to X-rays, such as wood, bakelite, or other plastic. The diaphragm has a radius of curvature about equal to the target-film distance. It is kept in motion throughout the exposure, and the timing is often interlocked with the exposure timer so that it is started in motion before the X-ray beam is started and stops after the exposure is terminated. The focal-film distance conforms to the range for which the diaphragm is made (often 30 to 48 in.) if fogging or grid shadows are to be avoided.

The geometry of X-ray shadows has been developed to a high state of perfection by medical roentgenologists as an aid to precise location of focal infection, foreign bodies, bone injuries, etc. Stereoscopic X-ray pictures have also been made and when viewed in a stereoscope yield a remarkably graphic device.

For dental use, small but powerful tubes are now mounted, together with high-tension transformer and filament transformer, in a vacuum-sealed lead case filled with oil. This construction renders the outfit shockproof and X-ray protective so that patient and operator are safe from electric shock or stray radiation. It also makes the use of dental radiography simple, convenient, accurate, and independent of climate, temperature, and humidity. Most dentists now possess an X-ray outfit as a part of their regular equipment, and diagnosis of the condition of teeth has become a precise matter.

Injury from X-rays, radium, and other radioactive materials was early found to result from exposure of living tissue to these rays. The cumulative effect of incidental irradiation received by early X-ray workers was not recognized until many of them had become true martyrs to science. Knowledge of the effects and control of radiation has now progressed to the stage where radiation in therapy and protection from stray radiation in industrial use are subject to precise measurement, and injury from either is inexcusable. It is fairly well established that interception of 1 roentgen of X-radiation (abbreviated r) per week will be tolerated by a normal person without ill effect. This corresponds to 10^{-5} r per sec for continuous exposure during a 7-hr working day. This of course applies to long-continued exposure of the body to weak X-rays. The human body may tolerate upwards of 500 r administered locally, provided a week intervenes before another dose is received. It may likewise tolerate two exposures of 400 r given 24 hrs apart. (The National Bureau of Standards Handbooks 20 on "X-Ray Protection" and 23 on "Radium Protection" afford information on this subject.) A simple method of providing knowledge of the exposure of personnel to X-rays is by means of a common paper clip fastened to the face of an ordinary dental film (not a slow one). After this film is carried for a working week by the worker, with the paper clip facing away from his body, the film should be developed and fixed. The absence of any darkening or image of the paper clip on the film indicates that the bodily exposure to radiation is safe. A slight shadow indicates borderline exposure, while a definite darkening indicates dangerous exposure. This should be regarded as a crude estimate which should be checked by actual measurement through the use of a dosemeter or mineometer, as suggested on page 1632. Furthermore, the foregoing procedure gives no knowledge of the injury that may result from exposure of parts of the body (*e.g.*, the hands) to localized radiation. Because of the greatly increased use of radioactive isotopes, weekly film-badge service is commercially available for monitoring of radiation dosage. Different-colored badges are sent to the customer each week, together with a report on the previous week's badges, which have been processed by the service laboratory after return by the customer.

Protection may be achieved by shielding the personnel with some material more or less opaque to radiation, such as sheet lead, of sufficient thickness to bring the radiation in the region to as low a value as required for safety. When sheet lead is used as a protective lining, its thickness will vary from $\frac{1}{16}$ in. for 100 kv to over 3 in. for 1,000 kv. For high voltages, from a few hundred kilovolts upward, concrete of sufficient thickness provides safety at less expense. For voltages in the neighborhood of 100 kv, the concrete of necessary thickness may be 50 to 100 times that of lead; while for voltages of 1,000 kv or so, ten times the thickness of lead may suffice. The thickness will depend on the aggregates and density of the concrete, and each case should be the subject of a separate study. Very complete protection is necessary in the industrial fluoroscopy of nuts, cereals, candy, oranges, etc., because the operators are exposed to stray radiation for hours every day, since such equipment operates continuously. Of course it is just as necessary to protect personnel against injury from gamma-ray emission from radium, radon, or other radioactive substances.

X-ray therapy soon followed the discovery that abnormal growths, whether warts or the more serious neoplasms, could be destroyed by X-rays with a dosage that the surrounding healthy tissues could tolerate. This treatment advanced to the deep-ray therapy where deep-seated neoplasms, even when adjacent to or in vital organs not susceptible to surgical interference, could be treated with much less hazard to the patient than would result from excision. It also developed that the X-ray was a valuable adjunct to surgical treatment. Irradiation of the circumadjacent organ or tissues is found to inhibit subsequent growth and spreading of excised malignancies.

Numerous workers in X-ray therapy have developed dosages for radiotherapy and geometries of application. Successive applications are often made from different angles terminating in the same spot at the seat of the malignancy, in order that this "cross firing" may traverse healthy tissue less frequently in successive applications. The dosages run from 2,000 to as high as 10,000 r and are spread over a sufficient period of time so that doses of 200 to 700 r may reach the accumulated total. The subject of X-ray therapy involves an extensive knowledge of doses and the technique of application and involves a very extended and specialized literature from which the experience and results of many workers may be learned.

Early in radiation therapy the gamma rays from radium and its decomposition products, especially radon, were used with varying degrees of success. There are many cases where such rays may still be used to advantage by locating the radiant material at the seat of the malady in what is often termed intercavity application. The radium salt is enclosed in a capsule or tube. This treatment is often combined with a more generalized radiation from X-ray beams.

Nearly all deep-ray therapy, as compared with superficial therapy, includes the use of filters composed of copper, aluminum, platinum, gold, or other material, singly or in combination, in order that the skin may be protected from the soft rays while the hard rays are projected to the deep-seated object.

The trend of deep-ray therapy for several years past has been toward higher and higher voltages. A million volts is not uncommon, and several million volts have been used. Two or three million volts approximate the quality of gamma rays. With the high-voltage Van de Graaff generators and betatrons operating at dekamillions of volts, the quality of gamma rays may easily be reproduced. Thus the quality and quantity of all natural radiation available may easily be exceeded. It is also probable that many new techniques will stem from the artificial radioactive isotopes made in the laboratories of atomic fission. One example of these possibilities is the use of radiophosphorus for the treatment of leukemia. Since phosphorus is selectively absorbed by the bones, an injection of the radioactive form will treat the blood and bone marrow at the seat of the malady. Other materials are being produced, and considerable development work in this field of therapy has been achieved.

Industrial applications of X-rays include examination and inspection of castings, welding, and food products, as well as X-ray diffraction in crystal and metallurgical analysis. The examination of castings and welds may be made either visually by means of a fluorescent screen or radiographically by photographic means. The examination of castings for production control gives the important information on molding practice in location of risers, gates, and chills, as well as temperature for pouring completeness, that cannot be achieved by sectioning. The fact that it is nondestructive gives it an advantage over the destructive methods but provides a production control that will aid in maintaining the original standards. With complex alloys it discloses shrinkage, tears, and cracks, as well as piping, gas cavities, inclusions, dross, and dendrites. This usefulness applies to steel and malleable iron, as well as nonferrous castings in aluminum, brass, bronze, or other alloys.

Since 1930, specifications of the Boiler Code Committee of the ASME have required the X-ray examination of welds of pressure vessels. Since fissures are usually in a plane perpendicular to the thickness of the weld, they may be detected in ½-in.-thick steel when they are only 0.5 per cent of the total thickness. In 3- to 5-in. steel they may be detected within 2 per cent of the total thickness. With the thicker plates, a diaphragm is necessary to prevent the scattered radiation from obscuring the trace of the defect. The destructive testing of a coupon gives no assurance that an adjacent section of the weld is without flaw; the X-ray testing of the completed weld gives assurance that the weld is as good as the test sample. Porosity, slag inclusions, and fissures are easily detected and when so located may be chipped out and rewelded. Of course, all the foregoing inspections may be carried out by radiographs which render a permanent record of the inspection.

Laws and the reputation of the manufacturer make positive and reliable inspection necessary in the food industry. It is often desirable that the completed package be examined. Here the X-ray enables the inspector to look through the object rather than at it. It is usual to have the product travel on a conveyor belt over the source of X-radiation and beneath a fluorescent screen, with the operator looking at the objects from a darkened booth or through a hood. A brilliant image of the object appears and usually with sufficient definition so that any lack of uniformity is immediately apparent. In this manner, imperfect filling of the package is recognized as well as defects or foreign bodies in the contents. Containers filled with candy, cookies, cereals, frozen fruits, or vegetables may be checked for completeness of packing or for foreign bodies such as pins, nails, stones, dirt, balls, etc., independently of magnetic or other physical properties except degree of transparency to X-rays. Bulk foods, such as nuts, beans, berries, and vegetables, may be examined for foreign materials and hollow hearts. Citrus fruits can be inspected for frost damage, crystallization, or pulpiness—a great improvement over the water-separation method, since much fruit discarded by that method would be saved. Meats are being inspected for foreign bodies and broken bones.

Another field of application assuming added importance is inspection by similar methods of fabricated articles, *e.g.*, shoes for proper nailing and lasting; rubber heels and plastics for positioning of metal inserts; wood products for knots or position of screws or other fastenings; electric fuses for loose connections; golf balls for concentricity of cores; tires for nails, wire, glass, breaks, or imperfections in the fabric. The list may also include storage-battery separators, insulating bricks, wire and cable, drugs in packages, small assemblies (for completeness), and many items of similar character. Small castings and other metal parts may be inspected on the conveyor belt in the same manner as the foregoing examples.

X-ray diffraction, which is now an essential tool of modern industry, was unknown four decades ago. Until 1912, the geometry of crystal lattices was based on knowledge revealed by visible light. The microscope, regardless of its power of magnification, cannot disclose any object smaller than the wave length of the light illuminating it. In 1912 the theoretical physicist Laue suggested that Friedrich and Knipping attempt diffraction of X-rays by means of a crystal. To this successful beginning, based on the assumed geometry of the crystal lattice, numerous experimenters have added much knowledge of crystal structure. Among these should be mentioned William Bragg and his son W. L. Bragg because they developed a method of crystal analysis which proved to be the basis of all further work. Simple structures, like rock salt and zinc blende, soon established principles of crystallography that could be extended to crystals of more complicated structure. Later the structure of metals, whose stability is based on the attraction between free electrons and positive ions, was studied. Pure metals have simple face-centered cubic structures, like copper, aluminum, and gamma iron; body-centered cubic structures, like radium, alpha iron, and delta iron; or closely packed hexagonal cubic structures, like zinc, tungsten, and magnesium. Some metals have phases of different structure, like the face-centered cubic structure of iron between 1100 and 1425°F, though it has a body-centered cubic structure outside this range. Alloys exist both as solid solutions and as compounds, and the structure is disclosed by their X-ray-diffraction patterns. In fact, our knowledge of crystals and metallic structures has nearly all been obtained by studies of X-ray diffraction.

In most cases the physical properties of a substance are determined by the arrangement of its submicroscopic particles or molecules. For example, heat-treating, cold-working, or a combination of the two will impart to a metal physical properties desirable for a specific use. By these methods their properties may often be changed through a range greater than that existing between two totally dissimilar metals. These differences are readily shown by X-ray-diffraction patterns. When one pattern is identical with another pattern obtained in the same way, the structures are identical.

Chemical properties of substances are also revealed by their X-ray-diffraction patterns. Thus it is possible to identify an element, distinguish whether it exists as a compound or a mixture, and determine whether it is amorphous or crystalline.

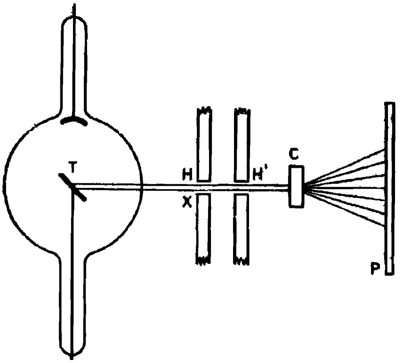

FIG. 28-17. Diagram of arrangement for X-ray diffraction.

From the foregoing discussion it is obvious that for research or production control in rubber, plastics, cements, paints, textiles, ceramics, metals, mineralogy, biology, physiology, pathology, and numberless other fields, it is possible to identify the constituents of a substance, determine their form, and predict their physical characteristics. In compounding, vulcanizing, or other processing of rubber, the structure and characteristics of the product can be determined and controlled. In rolling, drawing, or other working of metals and alloys, the structural changes attending these processes are at once determinable for production control. Precious stones and gems, natural and synthetic, can be differentiated and the best axis of orientation established for preparation for esthetic or mechanical purposes. The differentiation between normal and pathological tissues can be determined, as well as the effects of disease and medicine with their relations to bodily functions. These few illustrative cases indicate that a list of research and industrial uses of X-ray diffraction could be expanded indefinitely.

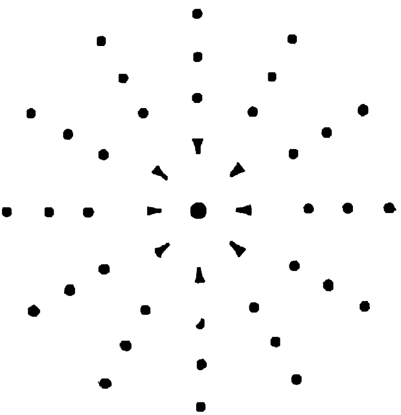

FIG. 28-18. Laue pattern.

Diffraction patterns are available only as photographs and are not suitable for reproduction in a book of this character. The interested reader can obtain numberless examples from manufacturers of X-ray-diffraction equipment. However, Figs. 28-17 to 28-20, which are diagrammatic in character, are introduced to explain the main features of this technical procedure. An X-ray source T, in Fig. 28-17, emits a beam of X-rays X through pinholes in two screens H and H' which traverse a crystal C and impinge on a sensitized surface P. The beam will be scattered as indicated, and in the case of a crystal the emergent rays will form a geometrical pattern, as shown in Fig. 28-18 or Fig. 28-19. The result shown in Fig. 28-18 was predicted by Laue and is called a Laue pattern. Figure 28-20 is a diagram of the atomic arrangement in a face-centered cubic crystal of a simple arrangement such as sodium chloride (NaCl). Figure 28-21 indicates the successive layers in this crystal. A ray of X-radiation will travel from *A* to *B*, and part of it will be reflected to *C*. Another ray travels over the path *A'B'C'*, a distance increased by the distance between the successive layers of crystals, multiplied by 2 sin θ, or formally,

$$n\lambda = 2d \sin \theta$$

where n = an integer
λ = wave length of the reflected X-ray
d = distance between the successive layers of crystalline structure

This is Bragg's equation and permits the correlation of X-ray wave length and crystal layers. By making use of X-rays having a known principal wave length, the dimensions of the space lattice in crystals can be determined. Conversely, when the dimensions of the crystal structure are known, the length of X-rays may be determined.

ULTRAVIOLET LIGHT

Ultraviolet light, being one of the constituents of solar radiation, has always contributed to life on earth. Foodstuffs, the fuels for all animal life, are produced by the action of sunlight on plants. Countless myriads of plant cells are vital laboratories for the synthesis of plant food. Billions of molecules in each cell are using solar energy, chlorophyll, and the cells' activities to produce food. Ultraviolet light is the chemically active constituent of solar energy. Its place in the electromagnetic spectrum is shown on pages 1624 and 1625. Light ceases to be visible at about 4000 Å, or 4×10^{-5} cm (1 angstrom abbreviated Å = 10^{-8} cm), and ultraviolet from the sun ends at about 2900 Å because of atmospheric absorption. At about 3400 Å, ordinary glass ceases to transmit any substantial quantity of ultraviolet. Quartz may be used until it, too, becomes too strongly absorbing, at about 1800 Å. Then fluorite may be used until a wave length of approximately 1200 Å is reached. Some workers have succeeded in measuring wave lengths as short as 50 Å, and the longest X-rays start in the neighborhood of half this value. The ultraviolet spectrum is ordinarily understood to extend from about 400 to 200 Å.

The emission of radiant energy results in three types of spectra: line, band, and continuous spectra. The physics of emission may be illustrated by the simplest case—line spectra from the single-electron atom of hydrogen. Three series of spectral lines were discovered, respectively, by Balmer, Paschen, and Lyman. Dark lines crossing the solar spectrum were seen by Wollaston in 1802; but Fraunhofer, who made the first measurements with a grating, recorded about 600 lines. The number has since been extended to more than 10,000. Under certain conditions the spectrum of hydrogen will exhibit a series of dark lines crossing it similar to Fig. 28-22. J. J. Balmer, in 1885, seeking to explain the regularity of the lines, found that the wave-length sequence could be described by a constant 3,645.6 which may be stated,

FIG. 28-22. General appearance of line arrangement in hydrogen spectrum.

$$\lambda = 3{,}645.6\,\frac{n^2}{n^2 - 2^2}$$

where n assumed the successive integral values 3, 4, 5, and 6. Rydberg later wrote the equation in the form,

$$\nu = \frac{1}{\lambda} = \frac{1}{3{,}645.6} \times \frac{m^2 - 2^2}{m^2}$$

When the numerator and denominator of the right-hand side of this equation are multiplied by 4 and λ expressed in centimeters, the equation becomes

$$1/\lambda = 109{,}720(1/2^2 - 1/m^2)$$

The factor 109,720 is known as Rydberg's constant and is designated by R. Later measurements have corrected it to 109,677.8 cm^{-1}.

Lyman, in 1906, discovered a series in the spectrum of hydrogen which may be represented by

$$1/\lambda = R(1/1^2) - (1/m^2)$$

and in 1908, Paschen discovered a series which may be represented by

$$1/\lambda = R(1/3^2) - (1/m^2)$$

Hence all the lines in the hydrogen spectrum may be represented by

$$1/\lambda = (R/n^2) - (R/m^2)$$

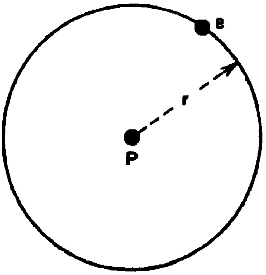

FIG. 28-23. Bohr's model of the hydrogen atom.

or the wave length is inversely proportional to the difference of its spectral terms. Bohr succeeded in devising an atomic model which gave a simple physical interpretation of these terms. Bohr's model of the hydrogen atom is shown in Fig. 28-23, where P is a central nucleus or proton with an electron e revolving in an orbit at radius r. It was assumed that

$$\Delta w = \nu h$$

i.e., that the change in energy Δw was equal to the product of the frequency of the radiation ν and Planck's constant h. Stated otherwise,

$$\nu = \frac{w_{n2} - w_{n1}}{h}$$

which gave the correct equation for the spectral series for hydrogen as well as Rydberg's constant.

Referring to Fig. 28-24, showing circular orbits for hydrogen, the normal state for the atom is at $n = 1$, or condition of minimum energy. No energy is emitted so long as the atom remains in this state. When the atom is bombarded by electrons or ions, the electron will be moved to an orbit further from the center. In a very short interval the electron returns to a lower energy level and emits energy in the form of light. In moving in to n_1, the Lyman series results; to n_2, the Balmer series; and to n_3, the Paschen series, as indicated in Fig. 28-24. The application of Bohr's theory to the more complex atoms becomes more complicated. The atomic number Z fixes the number of electrons in a given atom, and this determines its chemical behavior. If $Z = 11$, the element is sodium regardless of its atomic mass (see Fig. 28-25). Two electrons remain relatively close to the nucleus, and in a quantum state $n = 1$, or what is called the K shell. Eight electrons are in the quantum state $n = 2$, or the L shell. State $n = 3$ is the M shell. The electrons in any shell except the K shell do not have the same orbits, and the shell does not describe an energy level. The outermost electron, however, is responsible for the chemical and optical properties of the atom just illustrated. The optical spectrum of an element is a complex arrangement of many lines. The iron spectrum has thousands of closely spaced lines, and more than three thousand have been recorded for cerium.

The foregoing discussion has been applicable to line spectra resulting from single elements in the gaseous state. When elements are combined in compounds, the molecules emit more complicated groups of lines which have been called "band spectra." When energy is added to a solid so that it emits light covering a large spectral range, the lines will be suppressed or merged into a continuous spectrum. It should also be observed that, when light from a continuous spectrum is passed through an elemental gas, certain lines will be observed which agree with the lines which are emitted by the same gas. These are of the wave lengths to which its atoms are resonant and represent an absorption spectrum.

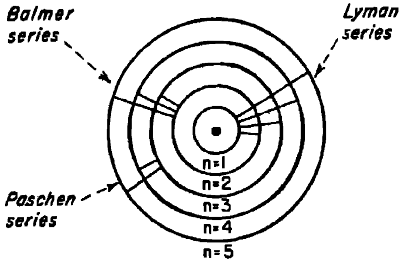

FIG. 28-24. Changes in energy state and spectral emission of the hydrogen atom.

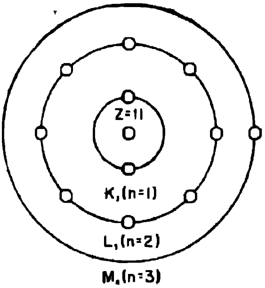

FIG. 28-25. Bohr model of sodium atom.

Sources of ultraviolet light commonly used are sun, arc, spark, and glow discharge. The sun provides an unlimited source of ultraviolet radiation, of which only the wave lengths above about 3070 Å reach the surface of the earth in the temperate zone in winter and 2970 Å in summer. The percentage of different wave lengths varies with the latitude and seasons, but a value of about 3010 Å can be taken as a fair average at a latitude of 40 deg. It has been found that ultraviolet rays shorter than 2950 Å are lethal to bacteria and destructive to living cells. In view of the fact that these conditions have existed during the development of life on the earth, they would appear to be in accordance.

Although an electric spark and an electric arc may appear to possess similarity, they are physically different. In a spark, electronic or ionic conduction takes place in the medium in which the spark exists. It is associated with ionization of the surrounding atmosphere under a high potential gradient. The spectrum partakes of the spectral characteristics of the ionized medium, and the ions may be singly, doubly, or even triply ionized. Spectral characteristics of the electrodes may be contributed as a contamination if the current is sufficiently high to cause their volatilization.

Under a sufficiently high voltage gradient with limited current, this spark between cold electrodes results in the current being carried by gaseous ions or electrons and becoming a glow discharge.

In arc conduction, on the other hand, the high-velocity arc stream is fed by vapor from the negative electrode or cathode moving at high velocity to the anode. The spectrum of the cathode material thus appears in the resultant light, and any characteristics of either the surrounding medium or the anode are incidental and contributed indirectly by heat luminescence.

Incandescent solids, such as the filament in an incandescent lamp operated at abnormally high temperature, may be used as the source of a continuous spectrum which includes the ultraviolet region. Soda-lime glass bulbs cut off the transmission at about 2900 Å, and lead-glass bulbs limit the use of this source to wave lengths above 3000 Å. High-temperature flames, excitation of gases by high-frequency electromagnetic fields, and some novel but cumbersome methods for the production of ultraviolet light have been used and found impractical.

Electric sparks are sometimes used as a source of ultraviolet radiation but mainly for the purpose of analyzing materials by spectrographic methods. A transformer with the primary wound for use on the usual power mains has a high-voltage secondary connected across the spark gap. A discharge will occur when 25,000 to 30,000 volts per cm (peak voltage) are impressed on the gap. An oscillatory or sustained discharge will occur if a suitable capacitor is also bridged across the gap, as indicated in Fig. 28-26. This condenser must, of course, have sufficient dielectric strength to withstand the maximum peak voltage. Iron or aluminum electrodes render valuable ultraviolet spectra with large numbers of reference lines. Equipment of this character is available from commercial manufacturers.

Carbon arcs date from their discovery by Sir Humphry Davy, at the beginning of the last century, who used a 2,000-plate battery and produced an arc 3 in. long between carbons. The carbon arc was an important illuminant for large areas during the last two decades of the past century where extensive areas were to be lighted. Other devices have superseded them for this use, and they are now employed where a high-intensity concentrated source is required. A highly actinic light is provided for such work as photoengraving and blue-printing where arcs are still frequently used. A d-c arc, because of the unidirectional high-velocity stream of vapor issuing from the negative electrode and impinging on the positive electrode, gives a very concentrated intense source of light. This intense spot is suitable for an application where it is to be placed at the focus of a lens or mirror. By placing the positive carbon in a horizontal position, use is made of its intense crater for such work as motion-picture projection and searchlights.

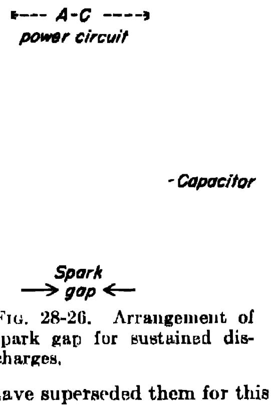

FIG. 28-26. Arrangement of spark gap for sustained discharges.

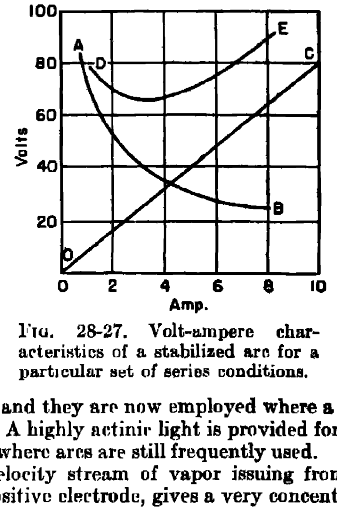

FIG. 28-27. Volt-ampere characteristics of a stabilized arc for a particular set of series conditions.

The volt-ampere characteristic of the arc should be mentioned relative to its operation. It will be observed by reference to curve *AB* (Fig. 28-27) that an increase in current accompanies a decrease in voltage. A constant voltage applied to the arc terminals results in instability over the entire range of current. The volt-ampere characteristic of a resistance (or reactance in the a-c arc) curve *OC*, as opposed to the arc characteristic, indicates a linearly increased current accompanying an increased voltage—a stable condition. The sum of the voltage at the terminals of the resistor and the voltage at the terminals of the arc, in series, indicated in curve *DE*, shows the arc voltage to decrease as the current increases until a current of 3.5 amp is reached. For any current beyond 3.5 amp, the current increases with an increase in voltage, and the circuit is stable. A greater resistance will stabilize the circuit at a lower current.

The plain carbon arc gives a spectral distribution ranging from 3000 to 15,000 Å or more, depending on current density in the arc, with the maximum energy output falling between a wave length of 5000 and 12,000 Å. Carbon arcs for industrial and therapeutic use are often formed by the use of so-called cored carbons. The carbons have a core of cerium, manganese, aluminum, iron, nickel, tungsten, chromium, titanium, or other metals or earths in some of their combinations or compounds. By this method the characteristics of the carbon arc may be made to meet specific requirements. By making use of some of the foregoing elements, a great part of the energy may be placed in the ultraviolet region, while the addition of certain other elements, *e.g.*, strontium, will move the maximum energy to the infrared region. Many carbons, covering a wide field of usefulness and various regions of the spectrum, are commercially available.

The mercury-vapor arc was brought out at the beginning of the present century by Peter-Cooper Hewitt, who applied it first to lighting. In this field its illumination produced a high visual acuity, but the color was objectionable for some uses. There are, however, still many applications, and extensive use is made of the mercury-vapor arc as an illuminant. It was soon realized that this device was a valuable source of ultraviolet light. To extend the spectrum beyond the cutoff point of glass, tubes of fused quartz were substituted. The mercury-arc spectrum extends into the extreme ultraviolet region with a line at 1849 Å. This wave length is below the point where quartz will transmit any considerable portion of the energy of the spectrum. Mercury-vapor lamps are therefore made by several manufacturers which use a quartz envelope which transmits a considerable quantity of energy in the far-to-extreme ultraviolet region. These lamps serve to meet the needs for chemical action in the ultraviolet region. Common glass transmits less and less of the spectrum in moving down toward 3100 Å where it is practically opaque to this wave length.

Therapeutic wave lengths are in the range 2950 to 3150 Å. Common glass transmits little energy between 4000 and 3100 Å, and the amount becomes less and less toward the shorter wave lengths until at 3100 Å the glass is practically opaque. The amount of energy transmitted at various wave lengths depends on the composition and thickness of the glass. Many special glasses have been developed which will transmit more or less of the spectrum in the therapeutic region. They are usually sold under names intended to connote their novel properties. Some are made in the form of windowpanes intended for use in solaria or situations where the sun's radiation may be applied to antirachitic therapy.

Many arc lamps are fitted with special therapeutic carbons for treatment of patients requiring ultraviolet therapy. An incandescent-arc combination lamp has also been developed for furnishing the therapeutic section of the spectrum—a so-called "sun lamp." This lamp is a combination of a tungsten incandescent filament and a mercury arc in argon, between tungsten electrodes, all enclosed in a special glass bulb. The special glass bulb will transmit some radiation at wave lengths as short as 2800 Å.

Photochemical processes cover a wide field in industry and are assuming increasing importance. The action of sunlight on oils in changing their physical and chemical properties has long been observed. This action can now be extended and accelerated by the use of ultraviolet light from artificial sources. Changes in physical and chemical character of various substances, in such a manner that some products will be improved and some injured, are produced by this agency. For example, olive oil is bleached by the photochemical action of light, while other oils, *e.g.*, cottonseed oil and soybean oil, may be darkened. Ultraviolet light has been used to remove objectionable taste and odor from cacao oil, and whale oil has been considerably deodorized. On the other hand, the rancidity of many products, such as potato chips, is favored by the accelerated oxidation caused by light. Artificial light may be used as a convenient means of testing for the determination of suitable packaging or coloration of wrappers that will render adequate protection against spoilage of products exposed to light.

In the textile industry it is necessary to determine the effect of light in reducing the strength and elasticity of fibers that may be exposed to this influence. It has been found that silk may lose 50 per cent of its strength on exposure to sunlight for 200 hr. Other fibers experienced decreased strength of the same order when exposed for increased times. The times increased through the series—jute, rayon, cotton, flax, hemp, wool—in the order given. The purer the atmosphere, the less the destruction.

It is general knowledge that the bleaching of textiles and paper by chlorine is accelerated by light (a fixed temperature assumed). In the textile and paper industries, tests for the rate of loss of color of dyed materials when exposed to light are necessary, *i.e.*, tests for light-fastness of dyes. Ultraviolet lamps are manufactured that are especially adapted for this use.

The testing of pigments in the paint industry falls in the same category as the testing of dyes. Accelerated weathering tests on oils, paints, and varnishes are possible by making use of carbon arcs developed for the purpose. These tests are also applied to synthetic varnishes and nitro- or ethylcellulose lacquers. Means of conducting accelerated tests on the oxidation of rubber and methods of protecting it from sunlight damage are developed by making use of artificial ultraviolet lighting sources. This is especially important in thin rubber coatings and membranes, such as those used for balloons. The spoilage of many pharmaceutical preparations is prevented by advance investigation of the effect of light and the application of suitable protection. The industrial applications of ultraviolet light for research and development are very extensive, and an extended discussion is not possible in a limited space; hence mention is made of only a few of the commonest examples.

Biological applications of photochemistry are very extensive and rapidly increasing as research in this field advances, although exact knowledge of the photochemical behavior of biological compounds is relatively limited. Work on enzymes, hormones, and products of pathological significance has been extensive. One of the important fields is the lethal action of ultraviolet rays in killing bacteria and molds. Prominent in this is the surface sterilization of foods and other expensive materials. The sterilization of air is extending from hospital operating rooms and corridors to schools and public buildings. Tests have shown that the region of bactericidal activity in the spectrum is between the wave lengths of 2960 and 2000 Å. The mechanism of the bactericidal action of the ultraviolet light (or, for that matter, any electromagnetic radiation) is not yet understood. Some interesting correlations for bactericidal action of different wave lengths have been published. There is some evidence that the absorption of a single high-velocity electron or a single X-ray quantum by a bacterium was sufficient to cause death. In the case of ultraviolet light the data seem to indicate a very low quantum yield when compared to the highly efficient X-rays. However, the ease of the use of ultraviolet light, together with its much lower deleterious effect on the higher animals, results in its extensive use as a bactericidal agent.

For a time the use of ultraviolet light for the sterilizing of drinking water seemed most desirable. The water itself would undergo no physical or chemical change, an overtreatment was impossible, the cost was not prohibitive, and the solution of air and other desirable materials was retained to preserve its pleasant taste. But since the objectionable features of chlorination have been largely removed by improved methods, the ultraviolet method has declined in favor. The extension of this method to the sterilization of milk has proved difficult, and the process is said to interfere with the production of activated ergosterol, or vitamin D_2. The process is not considered commercially feasible. Mercury-arc irradiation has been successfully used for bleaching flour. The growth of molds has been inhibited by the action of ultraviolet radiation on bread dough, and it does not interfere with the growth of the yeast cells. It is also effective in the bread-wrapping room to sterilize the baked bread and thus inhibit the growth of mold in the humid atmosphere of the package.

A considerable use of ultraviolet light rays between 2000 and 2900 Å has been made in the meat industry. Meat is benefited by aging in storage until the connective tissue within the muscle fibers is changed to gelatin by enzyme action, thus rendering it tender. But a relative humidity of 85 to 90 per cent to prevent excessive weight loss and storage above usual refrigeration temperatures favor the growth of surface mold. When mercury-vapor tubes, developed for the purpose, are included in the equipment of the tenderizing room, mold is prevented both by the direct action of the light on the surface of the meat and by the sterilization of the circulating air. The installation of the equipment in the sales refrigerator is said to reduce losses also from the deterioration of the surface of the meat.

Contamination in the operating room of a hospital is affected by the ventilation, the cleanliness of the room and the incoming air, and the number of occupants and the efficacy of their masks, as well as the contamination of their respiratory passages.

The danger in thoracic surgery is so great that operations in this region are postponed, when possible, until summer months. It has been observed that air-borne pathogenic bacteria are about ten times as susceptible to abiotic rays as the same bacteria when growing in a nutrient medium. This circumstance has made the use of abiotic or bactericidal rays effective in the protection of the patient. A battery of suitable mercury-arc lamps arranged above the operating table affords a very great measure of protection to the patient and because of its low concentration and inability to penetrate the skin will produce no known physiological effects. It has also been found that postoperative infection is avoided, wound healing is more rapid, and mortality is decreased more than 50 per cent. Moreover, the light is of a pleasant blue color but is of a negligible illuminating value. The development of the tantalum photoelectric cell, which responds to the abiotic wave lengths almost in accordance with their lethal effects, has made possible the application of this source of light with exactitude. This source of radiation is also applied to hospital corridors to prevent cross infection from transportation of infection across this barrier.

Therapeutic applications of ultraviolet light are treated in an extensive literature and will be only briefly mentioned here. Much of the literature is contradictory, which may be in part due to lack of proper limitation of the wave band concerned, either in its application or in the description of results. Ultraviolet radiation is often divided into four bands, with reasonable agreement on the division between scientific workers in the field. The four bands are fluorescent or near ultraviolet, 4000 to 3300 Å; biological or erythemal region, 3300 to 2800 Å; abiotic or sterilization region, 2900 to 2000 Å; ozone-producing region, 2000 Å to the limit of air transmission. The cutoff limit of quartz is near 1700 Å; that of air, somewhat below this wave length. The erythemal band of 3300 to 2800 Å is of therapeutic significance. There is general agreement on the broad aspects of the use of ultraviolet radiation for the treatment of such ills as rickets and surgical tuberculosis and for the improvement of the bodily vitamin D. But in other applications, such as altered circulation, changed respiration, modified composition of blood, or growth in the body, the literature is often controversial or contradictory. Proper control of wave lengths from the various sources and measurement of biological dosages may result in better agreement in the literature. Light of erythemal wave length is absorbed in very thin layers of the skin and under certain exposures results in erythema and pigmentation. Studies of the effect of light in this band have contributed to the development of many lotions and ointments for the prevention of sunburn. Most of them owe their efficacy to the incorporation of fluorescent material which at the surface of the skin changes ultraviolet rays to light of longer wave length. It is interesting to note that the lens of the eye filters out ultraviolet rays and thus protects the retina from their action. The use of heliotherapy in the correction of tuberculosis of bones and joints seems to be established, but there appears to be no unanimity as to the wave length of the curative ray. Even in antirachitic therapy one can only gather from the literature that an average of many opinions places the wave-length active in this sphere at an average value of 3080 to 3130 Å. In poultry husbandry it has been found that the hatchability of eggs and bone growth in chicks are improved by even short-time daily exposures of the flock to ultraviolet light. This assumes increased importance as the congested and artificial conditions of poultry raising increase.

INFRARED RAYS

The nature of infrared light will be evident by reference to the table on page 1624 and the previous treatments on X-rays and ultraviolet light. It is seen as electromagnetic radiation, to be classed with cosmic radiation, gamma radiation, X-radiation, ultraviolet radiation, visible radiation, short-wave radiation, and radiation in the broadcast band. It fills in the blank indicated in the series—the blank between the longest visible waves and the short Hertzian waves. The infrared starts where the long waves in the visible spectrum leave off, at 7600 Å, and extends to 500,000 or even 1 million Å. When the solar spectrum is considered, the wave lengths are 7600 to 30,000 Å, but terrestrial sources have yielded much longer wave lengths. The region of the spectrum in which we are concerned has the approximate energy distribution indicated in Fig. 28-28 for the five sources shown. Wein's displacement law shows that the maximum radiation intensity is inversely proportional to the absolute temperature of the black body, or

$$\gamma_{max} =$$

where γ_{max} is the wave length in microns at which the intensity of radiation is a maximum, and θ is the temperature in degrees Kelvin. These curves are approximate for the sun with a temperature of 5800 K; tungsten lamp, 2500 to 3000 K; carbon lamp, 2000 to 2200 K; flatiron, 525 to 600 K; boiling water, 373 K.

The industrial source of infrared rays is commonly incandescent lamps operated at a temperature that gives an economical production of heat energy without excessive lamp cost. Gas-operated infrared generators are used to a limited extent, mainly where a high heat concentration within a limited area is required. The incandescent lamp especially made for the purpose may be either tungsten or carbon filament. They respond to a need first brought to the attention of industry by a large application of this source of energy to the drying of automobile finishes by the Ford Motor Company in 1938. The shorter the wave length, the greaer the energy output, but in the case of incandescent lamps this is at the expense of lamp life. The filament, either tungsten or carbon, sublimates and is deposited on the inner surface of the bulb, and this process continues until the filament parts or "burns out." Photoflood lamps have an average life of 2 to 3 hr; projection lamps, 10 to 50 hr; general-purpose lamps, 750 to 1,000 hr; and street-lighting lamps, 3,000 hr when operating under rated conditions. They operate at successively lower temperatures in the order mentioned. Since the infrared lamp is designed to operate with its maximum output at as long a wave length as will result in good economy, its operating temperature is a few hundred degrees below that of the lamp designed for illumination, and the life consequently is extended to a 5,000-hr rating. Vibration and shock reduce the life of infrared lamps as they do that of illuminating lamps. Carbon filaments, for the same voltage, are shorter than tungsten filaments; hence the configuration of the finished filament may be made to approach more nearly a point source. When the filament is placed at the focus of a suitable reflector, a more uniform distribution of the light will result. The carbon filament, however, is more fragile, its life is shorter, and the energy output during its life is less than for a tungsten filament when referred to a given input.

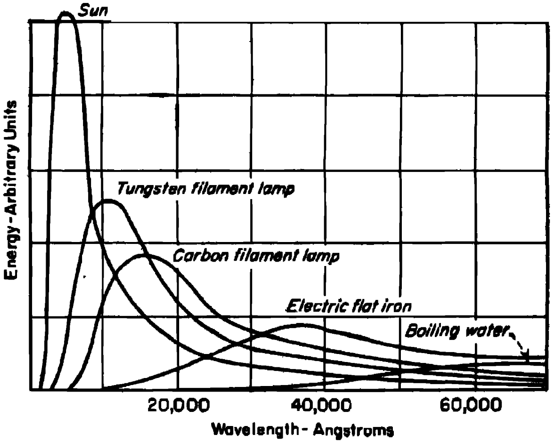

FIG. 28-28.

There are two general types of infrared lamps: those requiring a separate reflector and those with the reflector self-contained and sealed in. Those with the self-contained reflector are made in 250- and 375-watt sizes, both in an R-40 bulb. Common sizes without self-contained reflectors are 100-watt lamps in an A-23 bulb, 250-watt in a PS-30 bulb, 250- and 375-watt in G-30 bulbs, and 500- and 1,000-watt in a T-40 bulb. All but the 500- and 1,000-watt lamps may be used in the medium-screw porcelain receptacles, while the 500- and 1,000-watt lamps require medium bipost receptacles or sockets. Variation in applied voltage has the same general effects on output, life, efficiency, current, and power as it does on general-purpose illuminating lamps. The cheapest and best lamp for use, from the point of view of lamp cost and operating cost, is the 120-volt lamp. For use on 240- or 480-volt circuits it is generally cheaper to connect two or four 120-volt lamps of the same rating in series. Groups thus made up for series-multiple operation will have a somewhat shorter life than when burned in multiple on a circuit of their rated voltage. The life and operating efficiency, however, would exceed that of lamps specially made for the higher voltage and furthermore would have a lower first cost and lower operating cost. This is because of the fragility and lower efficiency of filaments made for the higher voltage. The approximate shape and size of the R-40 bulb with sealed-in reflector are shown in Fig. 28-29. Other bulbs, except the tubular with bipost base, are like those used for general-purpose illuminating lamps.

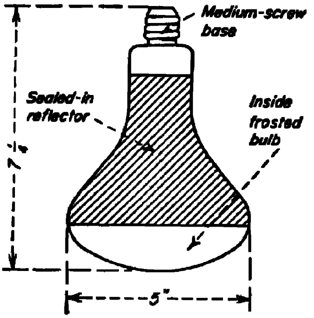

FIG. 28-29. R-40 infrared lamp with sealed-in reflector.

Gas-fired infrared generators usually consist of a refractory bowl or cup made of a ceramic or silica brick. In the center of the cup is placed a gas burner operated with air-pressure flames which leave the burner radially and scrub the refractory bowl, heating it to incandescence. They will release between 3000 and 5000 Btu/hr/sq in. of projected area. This is from 50 to 80 times as intense a heat as the 375-watt lamp will give. It fills a need differing from that met by the incandescent lamp. The gas-fired infrared generator is suitable for such work as brazing, annealing, hardening, forging, or melting of small volumes of metals. It is developed to concentrate a large amount of energy in a small space. It would also be suitable for use where the object to be heated moved so fast that electric heaters could not provide the necessary intensity of heat.

The equipment for the industrial use of infrared rays is in many respects similar to lighting equipment. It includes lamp holders, reflectors, current supply, means of getting the work to the radiant heat, and sometimes means of removing noxious fumes. The lamp holders must stand continuous high temperature. To have a useful length of life, the sockets must withstand continuous elevated temperatures. The insulation and resiliency of contacts must be maintained. Porcelain receptacles meet these requirements when lamps smaller than 500 watts are to be used. For the 500- and 1,000-watt sizes, which have medium bipost terminals, no suitable sockets have yet been developed. It is better at present to braze leads to the posts, using for the purpose asbestos-covered or other heat-resistant wire. These leads may then be connected to suitable terminals somewhat removed from the heat.

Coefficients of reflection vs. wave length for five of the most suitable reflector materials are plotted in Fig. 28-30. A good visible-light reflector is not necessarily a good infrared reflector. Not only has electrolytic gold, as plated on a metal surface, a good coefficient of reflection for infrared rays, but the surface retains its reflecting value well at temperatures that attend the use of infrared. Vaporized aluminum or silver, deposited on the reflector surface, is secondary in value and is used in the R-40 bulb. This surface operates in an inert atmosphere and retains its efficiency for the life of the lamp except as it is deteriorated by the deposits of the sublimated filament. Alzak stands next to gold for permanence and high reflectivity when exposed to the oxidizing influence of the atmosphere at high temperatures. The surface of the aluminum reflector is oxidized when manufactured. This protects the surface, which maintains a high reflecting coefficient after having been oxidized electrolytically. The specular finish has from 80 to 85 per cent coefficient of reflection, while the diffuse finish has a coefficient of 75 to 80 per cent. The specially prepared glasslike surface permits easy cleaning without damage.

The high production rates achieved by the use of infrared heating derive largely from the use of conveyors for moving the material, unless of course the material is in strip form, as paper, textiles, etc. For this rapid rate of handling, the work is carried through a tunnel of concentrated heat on a conveyor or overhead carrier. The lamps are preferably arranged so that uniform heat is delivered to the faces of the work by proper spacing of the lamps in the banks, and by making adjustment of the distance from the lamps to the work. For many kinds of work the conveyor is a belt of the mesh type, with the size of the meshes of course suited to the work. Where the work must be rotated in traversing the oven or tunnel in order that all faces of the work may be presented to direct rays from the lamps, the overhead type of conveyor is especially desirable. Where the speed of the heating process is subject to change, the conveyor drive must permit the adjustment of its speed to meet this requirement.

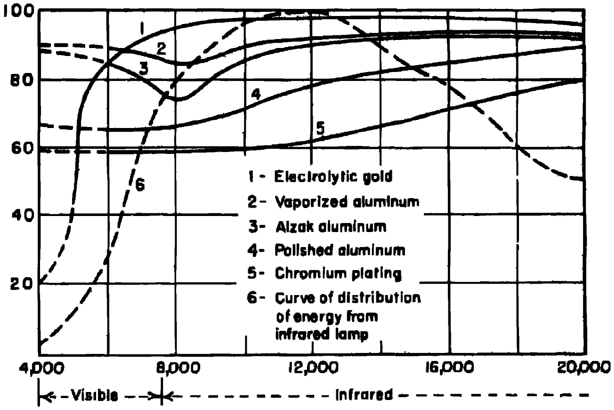

Fig. 28-30. Coefficients of reflection for some useful reflector materials.

The majority of installations are of the open type, but where noxious or flammable fumes are encountered, forced ventilation may be necessary. However, a satisfactory method of ventilating a great many installations may be to provide a hood above the lamp banks with a properly located stack and natural convection to discharge the vapors to the out-of-doors. Commercial infrared equipment is available which extends from a simple row of lamps, properly mounted and spaced, to a complete system of banks, tunnels, or ovens, complete with conveyors and adjustable-speed drives.

In planning an infrared installation, use is made of fundamental principles in heat calculation. For example:

A toy factory requires that steel wheels weighing 5.4 oz each be heated from room temperature to 150°F before tires are applied at the rate of 4,000 wheels per hour.

Specific heat of steel = 0.107
Room temperature = 68°F
1 kwhr = 3412 Btu
Weight of work = (5.4 × 4,000)/16 = 1,350 lb per hr
Energy required = 1,350 × (150 − 68) × 0.107 = 11,850 Btu per hr
Power required = 11,850/3,412 = 3.47 kwhr

Another example is as follows:

A textile plant requires that 100 yd per min of cotton cloth weighing 8 oz per yd have 2.3 oz of water evaporated from it when going into the drier from a room at 77°F. It is considered desirable to superheat the cloth 10°F.

Specific heat of cotton = 0.32 (approx)
Specific heat of water = 1.00

Heat of vaporization of water = 970 Btu per lb

Weight of cloth per hour: $(60 \times 100 \times 8)/16 = 3{,}000$ lb per hr

Weight of moisture per hour: $(60 \times 100 \times 2.3)/16 = 865$ lb per hr

For evaporation of moisture:

Raising temperature of water:

$$865 \times (212 - 77) \times 1 = 116{,}700 \text{ Btu per hr}$$

Evaporating the water:

$$865 \times 970 = 839{,}000 \text{ Btu per hr}$$

For heating the cloth: $3{,}000(222 - 77) \times 0.32 = 139{,}000$ Btu per hr

If the efficiency of vaporizing the water is 30 per cent,

Heat input for water $= (116{,}700 + 839{,}000)/0.3 = 3{,}185{,}000$ Btu per hr

If the efficiency of heating the cloth is 50 per cent,

Heat input for cloth $= 139{,}000/0.5 = 278{,}000$ Btu per hr

Energy input required $= 3{,}185{,}000 + 278{,}000 = 3{,}463{,}000$ Btu per hr

Power input required $= 3{,}460{,}000/3{,}412 = 1{,}015$ kw

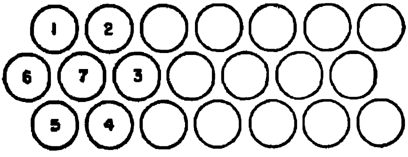

Fig. 28-31. Equilateral triangular lamp spacing.

In the foregoing examples the actual heat needed to accomplish the work was stated. Then efficiency was assumed and input to the lamp bank computed. In the first problem a certain mass was to be raised to a certain temperature in a certain time. The input to the lamps would depend on the efficiency of the lamps in converting electrical energy into infrared energy, on the efficiency of the surface used as a reflector, on the transmission losses between the lamps and the work, and on how well the work was arranged to intercept the heat rays. Approximately 10 per cent of the output of the lamp is in the visible spectrum; about 10 per cent of the input is converted from the bulb by the surrounding air; in the neighborhood of 2 per cent of the input is conducted to the base of the lamp and dissipated through the socket. Hence it may be expected that between 75 and 80 per cent of the input to the lamp, depending on the size, will be turned out as useful heat, and this is true. Reference to Fig. 28-30 will show that if an Alzak reflector is used, an average of some 80 per cent of the infrared will be reflected. This, then, will indicate that a maximum of $0.75 \times 0.80 = 0.60$, or 60 per cent of the input to the lamps, will be projected toward the work. When heating a mass, an efficiency of 50 per cent may be considered good performance, although in a closed tunnel or oven this over-all efficiency may be exceeded somewhat because use is made of the incidental heat convected by the atmosphere. When moisture is evaporated, there is a decreased efficiency, and 35 per cent may be considered good performance. In the example of the wheels, $3.5/0.5 = 7$ kw input would be a minimum requirement. Likewise in drying the cloth,

$$370/0.35 = 1{,}050 \text{ kw}$$

input would be the least required.

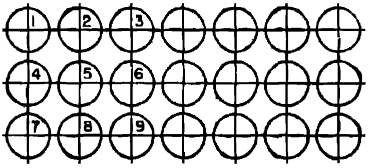

Fig. 28-32. Rectangular or square lamp spacing.

Infrared lamps should be arranged in uniform spacing, as shown in Figs. 28-31 and 28-32. The spacing in Fig. 28-31 is somewhat to be preferred to that of Fig. 28-32. Wiring of the lamps in the rectangular arrangement is easier than in the equilateral triangular arrangement. Essentially uniform heating may be had with either arrangement if the lamps are placed at the proper distance from the work, but with the equilateral arrangement uniform illumination will be secured at a shorter distance. A test bank may be readily assembled, with either arrangement, using lamps 1 to 7 in Fig. 28-31 and 1 to 9 in Fig. 28-32. Since infrared radiation obeys the laws of visible radiation, since both are generated at the same source, are projected together, and impinge on the same surface, the distribution of the light may be readily seen. In irregular work it is necessary to eliminate the shadows, which are easily seen. For a more exact survey, a meter similar to a foot-candle meter used in photography, but sensitive to the infrared range, is available. It is scaled to read in gram-calories per centimeter per minute. These units are of course easily converted into any desirable units of energy per unit surface per unit time, such as Btu per square foot per hour or kilowatts per square foot. The necessary degree of uniformity depends upon the application. To dry the surface of a thermally nonconducting material would demand much more uniformity than that of a metal where heat distribution would be aided by its conductivity. For test purposes, in connection with design, the R-40 self-reflecting infrared lamp will be found to be convenient and adequate. Arrangement and rating of larger lamps can easily be deduced from the test results found with the bank of R-40 lamps.

Surface finishing constitutes the most extended use of infrared heat because it is possible to achieve more rapid heating and an increased temperature of the work. This accelerates the three processes involved in curing a finish, *viz.*, evaporation, oxidation, or polymerization. Some finishes require only evaporation of the solvent, as lacquers, shellac, and other solution coatings. Others require oxidation in addition to evaporation of the solvent, and most oxidations are accompanied by polymerization. This is true particularly of synthetic or modified synthetic finishes. Many of these finishes are heat-hardening or polymerizing and are completely processed when they reach a final temperature. The rate of processing a finish is affected by the rate of heat absorption, which is at the highest rate with black, at the lowest with white, and with colors at an intermediate rate.

Industrial applications of infrared were first used in connection with the heating of surface finishes. The speed that can be attained by its use often pays for the increased thermal cost over other competing methods. It is not uncommon to have the time of a process cut to 10 or even 5 per cent of that required in convection ovens. Its use in textile plants up to the present has been principally as a booster or as a supplementary operation. It is convenient in this use to add or take away lamps as variations in the process demand. In the paper industry, much the same state exists. In ceramic industries, it is often replacing the biscuit oven for drying ware before it is glazed, as well as having utility in the decorating shop. The infrared driers provide a convenient and time-saving device for skin drying of green molds in the foundry. The heat can easily be taken directly to the mold, the risk of damage by movement of the green mold to the source of heat being thus avoided. There are doubtless many uses in the food industry and in other industries where the extension of its use would result in convenience and savings.

The therapeutic use of infrared rays extends back to the days when carbon-filament lamps were used for lighting. Physicians found the penetrating power of this radiation superior to various forms of conduction heat, such as that from hot-water bottles or heating pads. They have for some time past used the larger sizes of lamps, 1,000 watts or so, in clinics and hospitals. Many special forms of infrared generator for therapeutic use have been manufactured for years. The nonluminous heater for the production of wave lengths of 15,000 to 150,000 Å usually consists of a resistor operated at 750 to 1500°C, mounted in a suitable reflector or arranged in an ovenlike structure which may be used to surround the extremities or the torso as required. These oven devices are intended for superficial heating, since the long wave lengths supplied by them penetrate the tissues by no more than 0.1 to 1.0 mm. For deeper heating, the incandescent lamp is used in sizes from 60 watts to 1,000 or more. The maximum penetration of human tissue is at about 11,000 Å. By Wein's displacement law it may be computed that maximum emission of energy at this wave length is from a source operating at a temperature of 3550°C. This is not far below the filament temperature of the infrared incandescent lamps, which therefore furnish an excellent source of radiation for deeper heating in thermal therapy. This source, however, emits a considerable portion of its energy in the wave-length band beyond 15,000 Å, which is in the range of superficial heating. For the deeper heating the longer wave lengths are not wanted, since they cause discomfort. They may be readily eliminated by interposing a few-millimeter screen of water between the lamp and the tissues. This allows the lamp to be brought almost into contact with the body surface without discomfort, and this increases severalfold the penetration of the tissues by the shorter wave lengths.

The most evident physiological effect of infrared radiation on the body is vasomotor. When this heat is used, the blood vessels are dilated, and the circulation in the area increased. Much of the beneficial effect doubtless dervies from this circumstance. In addition there are chemical changes in the blood, the formation of tissue fluid which may leave the area as lymph, and changes in tissue metabolism. Some of these effects may be of such a nature in a particular inflammatory condition—redness, heat, pain, swelling—that the use of infrared is contraindicated. The estimation of its value requires a consideration of the possibility of capillary stasis and venous congestion. Any lesion of the sensory nerves requires that the infrared be used with the utmost caution. In every case the intensity of the radiation should be well within the tolerance and the sensation of heat comfortable.

POLARIZED LIGHT

The nature of polarized light should be reviewed before its uses are discussed. At the beginning of the last century it was considered that light consisted of longitudinal wave motion traveling in straight lines from its source through a transparent medium that pervaded all space. A quarter century later, the discovery of polarization of light acted to deny the theory of its longitudinal wave motion, but further study made use of this very phenomenon of polarization to establish the wave properties of light. Its early practical use was limited to mineralogy and crystallography. Its use as a technical tool is extending as more of its nature is revealed and equipment to make further use of it is developed.

At the risk of oversimplification of the actual facts, consider the illustration that will apply to Fig. 28-33. As the man's arm is waved up and down, sidewise, or at any angle, a wave moves along the rope from the man toward the post. When the motion is vertical, the vertical pickets do not limit the wave motion, but the horizontal ones do. When the two sets of pickets are at right angles, no wave will pass through both. Obviously if the vertical barriers were turned at any angle, the wave traveling at the same angle would pass through and be entirely stopped only if the direction of the pickets in the third barrier were athwart the motion of the wave. The first fence acts as a polarizer, the action of the second one is nil, and the third fence acts as an analyzer.

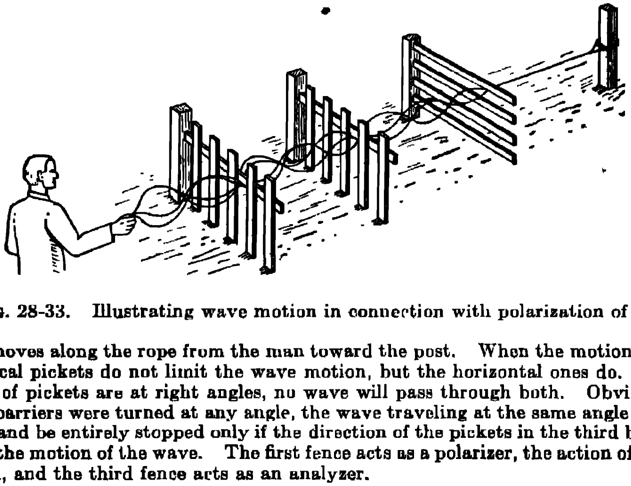

FIG. 28-33. Illustrating wave motion in connection with polarization of light.

The mechanism of light and its polarization is much more complicated than the simplified illustration offered in the foregoing paragraph. When light originates at an incandescent source, all wave lengths of visible light (as well as some of infrared and ultraviolet) are propagated at all possible angles and at many amplitudes. Vertical components of this light will pass through a polarizer with its polarizing axis placed vertically, and horizontal components will be cut off. If a second polarizer is placed beyond the first, with its polarizing axis located vertically, light will be passed as through the first one. If the second polarizer is placed with its axis horizontal, all the light will be extinguished by it. If the second polarizer is turned at any angle between vertical and horizontal, a partial quantity of the light will be transmitted depending on the angle. The second screen is called an analyzer. These arrangements are shown in Fig. 28-34. It will be observed that monochromatic light—light of a single wave length—is much less complicated in its physical aspects than the heterogeneous white light. Also, that polarized white light still possesses the heterochromatism of white light.

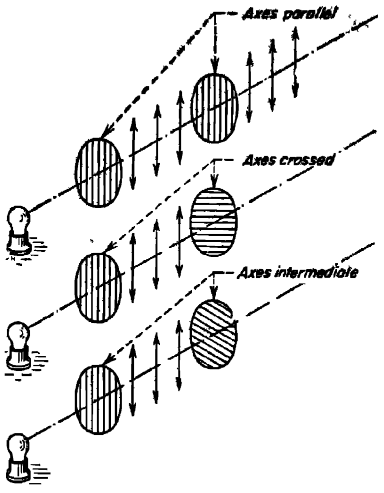

Fig. 28-34. Polarizing and analyzing screens.

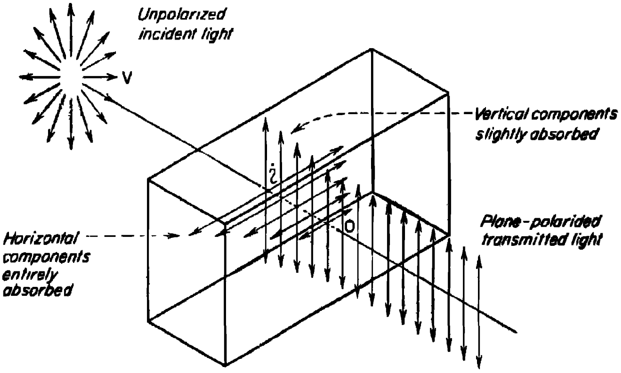
In Fig. 28-35, *V* represents a vector diagram of light waves of a single amplitude but random angles in a ray of light. The block *AB* represents a polarizer, such as the anisotropic crystal tourmaline, which possesses the property of double refraction and hence will polarize light. The unpolarized light enters the crystal at *i* and emerges at *O*. All vertical vibrations are transmitted with some absorption; the vertical components of the inclined vibrations are also transmitted in the same manner; the horizontal vibrations are absorbed; and a beam of plane-polarized light emerges at *O*.

Nicol prisms were originated in 1828 by the Scotch physicist, W. Nicol. The prism consists of an Iceland-spar crystal cut and cemented with Canada balsam in such a way as to deflect the ordinary ray and transmit the extraordinary ray. This was the most common polarizer until a few years ago and is still used where the best precision is required. In Fig. 28-36 the plane faces are on the plane *abcd*, and this figure also shows the paths of the rays. In 1852 an English physician, W. B. Herapath, discovered that crystals of sulfate of iodoquinine, later called herapath, would polarize light very effectually, but the crystal would disintegrate into useless dust at the slightest shock. About seventy-five years later, Edwin H. Land, while an undergraduate at Harvard, devised a scheme for preserving innumerable tiny crystals of herapathite in a plastic-film matrix which would also maintain their proper orientation and alignment. This film is usually mounted between glass plates for protection and ease of handling and is the Polaroid now commonly used in most applications where the use of polarized light is embraced.



Unpolarized incident light

O
Plane-polarized transmitted light
Horizontal components entirely absorbed

Fig. 28-35. Polarization by a crystal polarizer.

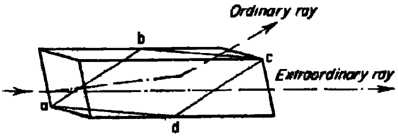

Fig. 28-36. Nicol prism.

There are many natural occurrences of the polarization of light. Light is polarized by its impact on a glass surface at an angle of 57 deg from normal. The index of refraction of ordinary glass is 1.54. The polarizing angle then becomes 57 deg when the simple equation

$$n = \tan \alpha$$

is considered, where n is the index of refraction, and α is the polarizing angle. Polarization by reflection is indicated in Fig. 28-37. This polarization takes place also when light strikes the top of a desk, drawing board, book, linoleum, concrete pavement, roadway, and other nonconducting surfaces at an inclined angle. The extent of polarization is greatest when the angle is near the polarizing angle for glass. This type of polarization is not usually recognized; for to be observed, it must be seen through an analyzer or polarizing screen properly oriented. Most of the surfaces named are usually seen in a horizontal position; hence, for extinction, the polarized rays must be viewed through a polarizing screen with its plane normal to the angle of reflection and its polarizing axis vertical. This phenomenon is the reason for the use of polarizing screens arranged as spectacles to eliminate or reduce glare on streets and roads. It is also the reason for controlled polarized illumination for inspecting benches, drafting tables, desks, and similar surfaces. The simple, relatively rugged screens of Polaroid of large area now available render such applications practical.

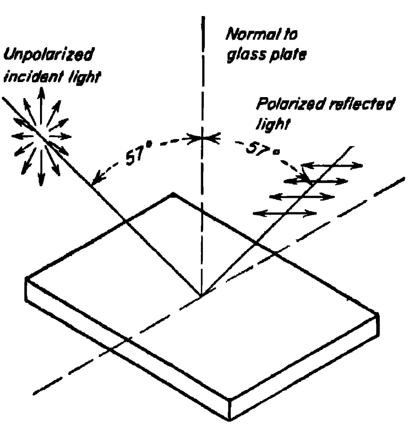

FIG. 28-37. Polarization by a plane glass surface.

Many years ago it was proposed that the discomfort resulting from glare in night driving be eliminated by the use of polarized light. At that time no device for bringing it about was available. The invention of Polaroid a few years ago makes this improvement in night driving feasible. In its adoption, polarizing screens would be applied to head lamps and windshields of cars, with the axis of the screen at 45 deg from the horizontal and inclined, say, from the operator's lower left to his upper right. This would place the polarizing screens of any oncoming car at right angles to the operator's viewing screens. The operator would see objects lighted by his own lights, but the polarized light from the headlights of the oncoming car would be stopped by his own polarizing windshield. Automobile-headlight glare could be eliminated if all cars were equipped with polarizing equipment. The combination of Polaroid and sealed-beam headlights makes this desideratum possible, but automobile manufacturers must provide the equipment and double the size of the present generators in order to initiate the change.

Small particles in a liquid or gas will "scatter" light waves and cause polarization. Short waves are scattered more than long ones; hence the sky appears blue to the observer. If a bright blue sky be observed through a polarizing screen while the analyzer, or viewing screen, is slowly rotated, the light will be found to be noticeably polarized.

Applications of polarized light fall into two categories: one where the initial polarizing process is natural, the other where the polarizing process is artificial. In both cases another polarization process, by means of an analyzer, is required to identify the polarization.

Sunglasses are really analyzers with the polarizing axis vertical and serve to reduce the glare by eliminating the natural horizontally polarized component.

When the light causing glare is from an artificial source, as in an office or drafting room, the glare from horizontal polarization may be eliminated by using only vertically polarized light for illumination.

Stereoscopic pictures may now be made in pairs, with light polarized at 90 deg for the making of each pair. A process has now been developed, called the vectograph, in which the picture with one direction of polarization is on the front of the film, the other on the back. When projected on a nonpolarizing screen and viewed through polarizing spectacles (really analyzers), the observer's eyes fuse the two images into a single three-dimensional impression.

Polarizing filters that may be rotated, when applied to binoculars, enable the user to eliminate the glare reflected from water or sky, as well as to adjust the density of the transmitted light to the brilliance of the scene being viewed.

Much of the glare from the sea, or other bodies of water, is highly polarized. Windows equipped with polarizing filters will permit the vision of a water surface with greater clarity and comfort.

Railway-coach and airplane-cabin windows have been fitted with vertically polarizing disks fixed in position to stop the glare reflected from horizontal surfaces outside. An inner disk, controlled by a knob enabling the passenger to rotate it, was added, and the combination provided a variable-density window giving him any amount of brightness control desired. Variable-density sunglasses have been made with double lenses operated on the same principle.

Polarizing screens are now available for use over camera lenses, and by their use sky brightness and glare may be controlled in the manner described for similar processes in the foregoing paragraphs.

Several applications in the ocular field have been made. One is an improvement that eliminates disturbing reflections in the ophthalmoscope; another device permits independent images to be formed in the patient's two eyes for the purpose of detecting an unusual eye defect; and a device has been made to test the sight of malingerers who claim that the sight of an eye is destroyed when it is really in good condition.

A gunsight has been developed which utilizes the interference pattern created by a section of calcite or sodium nitrate between two crossed polarizers. When the sight is used, the object is made to appear in the center of a series of rainbow-colored concentric rings if the gun is trained on the object seen through the center of sight.

Polarimeters for determining densities of many chemical solutions by their optical activity—particularly sugars, when the instrument is called a saccharimeter—have been in use many years. The polarizing microscope has likewise been an important tool for the mineralogist and crystallographer, and much of the useful knowledge of minerals, gems, and crystals has been developed by the use of this precise instrument of measurement.

Photoelastic stress analysis is an important use of polarized light. An isotropic material becomes doubly refracting when submitted to unsymmetrical strain. A common example of unsymmetrical strain is produced when glass cools spontaneously. Strain sufficient to cause it to fly apart is often produced when the object is spontaneously cooled. Annealing relieves the strain, and the glass is then isotropic. Imperfect annealing is readily detected when the glass object is viewed in a polariscope. The polarized light is supplied by a suitable illuminant and a polarizing screen. The glass object is placed so that the polarized light passes through it, and it is viewed through an analyzer which may be another polarizing screen or a pair of polarizing spectacles. The appearance of light and dark bands indicates a condition of stress. These stresses are set up in the glass as it contracts on cooling and can be prevented by cooling the article slowly. If stresses exist in a finished product, they may be detected by a polariscope and removed by annealing.

Photoelastic stress analysis or photoelasticity represents an extension of the strain testing of glass. By this method, stress computations may be checked or stresses in an object analyzed when computation is too lengthy or cumbersome. The method is to make a model of the article from some transparent isotropic material such as bakelite BT-61-893, catalin, or celluloid. This model is then loaded and viewed between crossed polarizers. In a simple flat object like a beam or ring, where two-dimensional analysis will suffice, the stress bands are readily viewed or recorded photographically and studied. If a dissymmetrical object is to be studied in three dimensions, it is possible to load a suitable model made from a thermosetting plastic while in a heated condition, cool it while under load, and thus freeze the stress patterns into the model. Thin sections may then be made, polished, and studied. This method would also be applicable to the study of dynamic stresses due to rotation. The model, while hot, would be rotated and cooled to room temperature while still stressed. In most cases, however, sufficient knowledge may be gained from the study of representative sections in two dimensions. The actual thickness of the sections is immaterial, but a common thickness employed is ¼ in. The faces of the model should be polished for good resolution, although satisfactory results have been obtained by other methods, such as coating the surfaces with oil or lacquer. Sheets of plastic with polished surfaces may be obtained from manufacturers or dealers. The edges of the model must be carefully machined perpendicular to the face. It is good practice to rough the piece out to within 1/32 in. or so of the boundaries and then complete shaping of the remainder by light cuts, avoiding heating. For the most accurate stress determinations, the model should be analyzed a few hours after completion before the edge effect may appear.

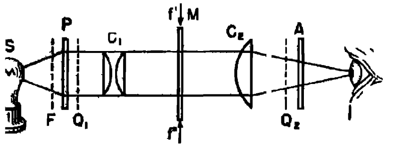

Fig. 28-38. Stress analysis in a plane model by means of polarized light.

When the loaded model is viewed in a polariscope, bands will be observed following the lines of constant principal stress. They result from the material becoming birefringent when stressed. Plane polarized light will be split into two components, each parallel to a principal stress: one, tension or compression; the other, shear. These two components travel through the stressed material at different velocities. If on emergence they are recombined by an analyzer, they produce isochromatic lines because they are out of phase. The amount that the components are out of phase depends on the magnitude of the stress in the model at that point. Where the plane of the entering polarized light coincides with the direction of a stress, that ray passes through the model without change in direction and

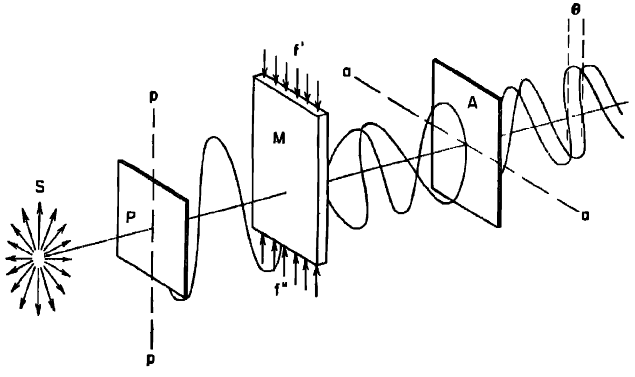

Fig. 28-39. Path of light waves in polarized light stress analysis.

is cut out by the analyzer, thus showing a black line. The black line formed is isoclinic. The other component shows bands of color when white light is used, owing to the merging of the successive isochromatic lines. When monochromatic light is used, the isochromatic lines appear black, and resolution of stresses to higher orders is made possible. With the use of either white or monochromatic light, bands appear along the lines of constant stress. If a given load produces one band in the object, double the load produces two bands, and each equal increment produces an additional band moving outward from the point of origin. The first line that appears is said to be of the first order; the second, of the second order; etc. When heterochromatic light is used, the colored bands tend to become confused at about the sixth order. By making use of monochromatic light, lines of an order as great as the twelfth or fifteenth may be resolved. This nears the elastic limit of most photoelastic materials.

In Fig. 28-38, a source of light S projects light through a polarizer P. The condensing lens C_1 directs the light in parallel rays through the model M, loaded with a force f'-f'', to the condensing lens C_2 which converges the rays passing through the analyzer A. An eye or camera at E will receive the rays. A filter may be interposed at F to introduce a band of monochromatic light, or a suitable monochromatic source may be introduced at S. At Q_1 and Q_2, quarter-wave-length plates or wedges may be used to remove the isoclinic lines when only isochromatic lines are wanted. When only isoclinic lines are wanted, a rapid relatively fine-grained panchromatic plate or sheet film capable of responding to the color of the monochromatic source may be used in the camera at E. For records of the colored lines, it is of course necessary to use a color-sensitive material. The three-color mosaic screens were formerly used, but now one of the many color films may be used. The diagram in Fig. 28-39 supplements Fig. 28-38 in illustrating the essentials of the process.

MAGNETISM

The lifting magnet appeared in industry about the year 1900. Three types have evolved: the circular or annular type, the rectangular type, and the bipolar type. Their construction is indicated in Figs. 28-40, 28-41, and 28-42. A coil surrounds a central core, and when energized by direct current, a high flux density is created in the poles. The highest feasible flux density is desirable because the pull of a magnet, for a fixed area of poles, is proportional to the square of the flux density,

$$F = B^2A/8\pi$$

where F = force exerted, dynes
B = flux density, gausses
A = area, sq cm

In engineering units,

$$P = B_i^2A_i/(72.1 \times 10^6)$$

where P = pull, lb
B_i = flux density lines per sq in.
A_i = area, sq in.

In Figs. 28-40 and 28-42, the steel casting—of high permeability—furnishes a housing of substantial character, as well as pole and yoke. The housing is provided with wide fins to add strength and cooling surface to the structure. The cover plate is made from manganese steel, which withstands the pounding and abrasive action of loads. It is also nonmagnetic and does not short-circuit the flux path, which would destroy the efficacy of the magnet. The use of lifting magnets includes the handling of miscellaneous scrap, pig iron, borings, and turnings, and almost all ferrous materials, even to recovering steel lading from sunken barges. A common use is the lifting of a skull-cracker ball, 25 tons or so, with the larger magnets. After raising to the proper height, the magnet is deenergized and the ball dropped to break the scrap beneath it. The same magnet then picks up the scrap and loads it on cars. The bipolar magnet is used for handling orderly piles of rails, blooms, billets, structural shapes, pipes, or other steel products in stockyards and is used singly or in pairs. The rectangular magnet shown in Fig. 28-41 is not subjected to such severe service as the steel-clad magnets of Figs. 28-40 and 28-42; hence its coils do not require the heavy steel housing of the ordinary lifting magnet. It is used for handling flat-surfaced materials such as billets, slabs, and blooms and is not subject to weather.

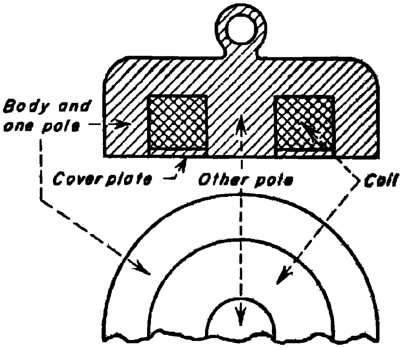

Fig. 28-40. Lifting magnet, annular type.

When a magnet is demagnetized to discharge its burden, the breaking of the highly inductive electric circuit is accompanied by a high-voltage inductive discharge. To prevent this and the consequent damage to contacts and insulation, a discharge resistance of suitable value is connected across the terminals of the coil before the circuit is opened. An instant later, the current is reversed to demagnetize the magnet and clear it entirely of its load. The controller is often equipped, especially on large magnets, with a series resistor which reduces the current in the magnet to a much lower value, sufficient to retain the load after it is once lifted. These controllers may be either hand-operated or of the automatic magnetic-contactor type.

Magnetic chucks are extensively employed when machine work is to be held for a grinding or light tooling operation. They offer a refined method of holding nice work that is magnetic without marring or distorting it. They cannot be used on nonmagnetic material. Two types of magnets are used: permanent magnets and electromagnets. They are of two different forms: circular for lathe and rotary-grinder service and rectangular platen form for plain or surface grinders and milling machines. The development of aluminum-nickel-cobalt magnet steels has introduced the feasibility of making excellent magnetic chucks by employing permanent magnets. This makes it unnecessary to provide direct current, or any current for that matter, and yet have a chuck with a holding force approximating that of electromagnetic chucks. The working of the permanent-magnet chuck will be understood by reference to Fig. 28-43. Strong permanent magnets are arranged to alternate with steel strips of high permeability, as shown in the figure. In Fig. 28-43*a*, the magnetism furnished by the magnets leaves them at the top and passes through the steel top plate, then

Table 28-2. Some Approximate Data Relating to Magnets

	Nominal diameter, in. (load, lb)						
Diameter	30	36	42	48	54	60	66
Billet or slab	15,000	22,000	30,000	40,000	50,000	60,000	75,000
Pig iron or heavy scrap	630	800	1,200	1,500	2,000	2,500	3,000
Skull-cracker ball	5,000	6,500	7,500	12,000	15,000	18,000	20,000
Light scrap	300	400	600	750	1,000	1,250	1,500
Weight of magnet, lb	1,200	1,800	3,000	4,000	5,700	7,800	9,500
Current, amp, at 220 volts	1.7	4.4	5.6	7.7	8.8	11.0	13.2

through the work, returns down through the top plate, the soft steel strip to the sole plate, and back to the opposite end of the magnet. The flux is confined to the desired path by means of the nonmagnetic separators. The magnetism thus induced in the ferrous work results in a strong attractive force between it and the magnet poles, thus holding it firmly to the surface of the magnetic chuck. To detach the work, the magnetic structure is shifted to the position shown in Fig. 28-43b. When the magnets are in this position, the magnetic flux passes through the top plate without entering the work, and the holding power is withdrawn. The shifting of the magnets is accomplished by a lever which actuates a rack and pinion, or other mechanism, to move the magnets between the ON and OFF positions. An arrangement similar in operation is employed with the circular chucks, except that a key is inserted in a suitable opening and withdrawn when the shift is accomplished. All the chucks are made with precision, and the plane faces of the top and bottom parallel. Setting up the work is greatly simplified, especially where a number of thin strips or washerlike objects are to be ground to a uniform thickness at one time.

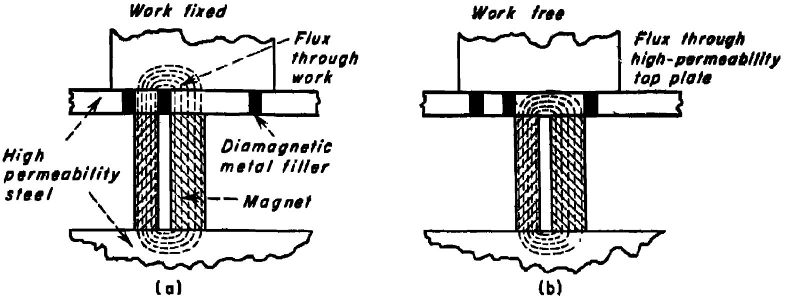

Fig. 28-43. Magnetic chuck. (a) Work fixed. (b) Work free.

The electromagnetic type of chuck has a structure that is represented in Fig. 28-44. All the steel or iron parts are of high permeability so that as much as possible of the magnetomotive force may be made effective on the work. The magnet cores, situated between the top plate and the sole plate, are wound with magnetizing coils, as shown.

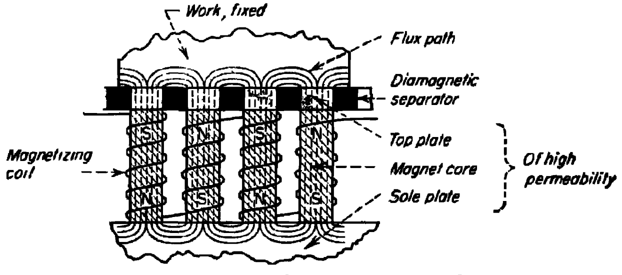

Fig. 28-44. Electromagnetic chuck.

The windings are connected in such an order that the poles at a given end alternate between north and south, and flux is caused to traverse the workpiece somewhat as shown in the figure. The work is thus held firmly. To detach the work, a reversing switch is used to open the circuit and reverse the direction of the current in one quick movement. If properly timed as to length of dwell in the reversed position, the flux reversal kills the remanent magnetism, and the work may be removed from the chuck in a demagnetized condition.

It is not always possible to demagnetize a material of high retentivity entirely when removing it from an electromagnetic chuck. Since no reversal occurs when objects are removed from a permanent-magnet chuck, some magnetism is retained.

This is troublesome in the case of tools, particularly cutting tools, since the swarf will interfere with vision of the working of the tool, as well as cause it to jam, and result in spoilage of work. In the days when only d-c dynamos were used, attendants and others soon learned that the stray flux from the strong bipolar fields destroyed the timekeeping qualities of their watches by magnetizing them. They also soon learned that the same field which did the damage could be employed to undo it. This was accomplished by suspending the watch from a string passed through the bow. As it hung vertically, the string was twisted. The watch was then suspended in the stray field and rotated in the field as the string unwound. This subjected the magnetized parts of the watch to a strong alternating flux; and if the watch was withdrawn while rotating, it would be found to be demagnetized. This same method may be applied to any other small parts, but it also illustrates the principle involved in demagnetization. The magnetized material is subjected to an intense rapidly alternating flux (25 or 60 cps is useful), and the field is decreased in value to zero while it is still acting. This may be simply accomplished by inserting the object in a solenoid energized with an alternating current and effecting a reduction in current until it reaches substantially zero. A convenient device for use in connection with magnetic chucks is a surface consisting of a divided flat plate connected to the two limbs of a laminated silicon-steel core energized with alternating current of commercial frequency. Pieces larger in area than the surface of the plates may be moved about while in contact with them, so that the alternating flux will act on all portions of the magnetized surfaces.

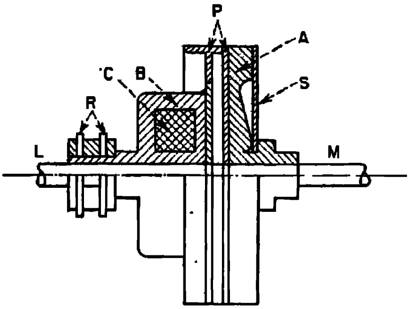

Fig. 28-45. Elementary form of magnetic clutch.

Magnetic clutches represent an important industrial use of magnetism. One type of single-plate, dry-type, magnetic clutch is shown in the elementary sketch, Fig. 28-45. Current is supplied to the magnet coil *C* by means of the collector rings *R* which revolve with the body *B* and collect current from stationary brushes not shown. To engage the clutch, current is supplied to the coil *C*, which attracts the movable armature *A* against the restraining action of the spring *S*. The spring *S* normally holds the armature from contact with the friction-plate assembly, thus allowing the clutch to run free. On energizing the magnet, a substantial pressure is applied to the assembly *P* which consists of a friction plate and pressure plates faced with treated woven-asbestos brake lining. Multiple-disk clutches are also made which greatly increase the effective area of the driving surfaces for a given body diameter and thus maintain a low ratio of moment of inertia to driving torque. The magnetic clutch possesses distinct advantages for coupling many machinery drives. It may be operated by a push button or small remote-control switch at any desired distance from the clutch; there are no levers or other mechanical linkages necessary to engage the clutch; the only wearing parts are the friction plate and rugged facings which are easily renewed; a smooth gradual engagement of the clutch is ensured by the exponential increase in current in the inductive circuit, even though full voltage is applied when the clutch is energized. The current increase depends on the familiar equation governing the increase of current in an inductive circuit,

$$i = E/R(1 - \epsilon^{-(Rt/L)})$$

where i = current at any instant of time t
E = applied voltage
R = resistance
L = inductance of the circuit
ϵ = base of the hyperbolic logarithms

The magnetic clutch can also be used as a torque-limiting device. The driving torque of the clutch depends on the pressure applied to the friction disks, which in turn depends on the current. If a limit is placed on the current, a corresponding limit is placed on the torque. Any torque exceeding this limit causes the clutch to slip. When slip occurs, the circuit may be opened by mechanical action or by thermal action from the heating of the pressure-plate system. Very little energy is necessary for the operation of the clutch; it may vary from something in the neighborhood of 10 watts per hp for small or low-speed clutches to as little as 2 or 3 watts per hp for large or high-speed clutches. An effective arrangement for reversing service consists of an armature on the driven member and clutch bodies revolving in opposite directions for each of the two driving members. Either clutch may be engaged by energizing the proper coil, and electrical interlocking is easily and effectively accomplished.

The magnetic brake in one form (multiple-disk) is not unlike the magnetic clutch described in the foregoing paragraph. The fundamental difference is that the spring is normally acting to set the brake; *i.e.*, the brake is normally on. The coil of this brake, when energized with direct current, is usually in series with the armature of the motor and is released whenever the armature is energized. (It cannot be used in this manner for a-c service because of the necessarily high inductance that would be inserted in series with the armature.) This brake finds its principal use on the motor shafts of electric cranes and hoists operated by direct current. The motor has an extended shaft on both ends to accommodate the driven machine and the brake stops the motor within a few revolutions when the current is cut off. The brakes are made in the dry type, with treated-asbestos friction disks rubbing on steel plates; and in the oil-immersed type, with fiber friction disks rubbing on brass plates. This type of brake is particularly adapted to severe service conditions because all wearing surfaces and moving parts are entirely enclosed. Arrangement of the operating coil in series with the armature is particularly desirable in hoisting service, since this requires that the armature be energized to hold the load before the brake is released. To obtain superior braking and magnetic-contactor service, the use of direct current is sometimes dictated. Steel-mill machinery, hoists, cranes, lift bridges, turntables, conveyors, and other applications where it is necessary to stop a load quickly and hold it belong in the foregoing class.

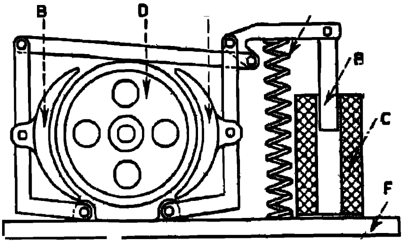

FIG. 28-46. Drum-type magnetically operated brake.

The drum type of brake with shoes is shown in Fig. 28-46. This type of brake is of very general application and suitable for elevators, cranes, bridges, door and window operators, printing presses, rotating machines, etc. It is solenoid-operated and designed to stop a load quickly and hold it but is not intended for lowering loads. The drum *D* is mounted on the shaft to be stopped, usually on one end of the doubly extended shaft of the driving motor. The brake shoe *B* should be so constructed as to eliminate chatter and so placed as to eliminate drag. It is usually spring-set by a spring *S*, electrically released by a solenoid *C*, and normally in the applied position. The system of levers is operated by the plunger *P*. In small sizes, gravity sometimes takes the place of a spring for setting the brake. It has the advantage of a constant ever-present force but the disadvantage of requiring more cumbersome devices for adjusting the torque. In small to moderate sizes, say from a few pound-feet to a hundred or so, this brake is solenoid-operated from full-line voltage for either d-c or a-c service (25 hp at 1,150 rpm = 114 lb-ft). Larger sizes, up to many thousands of pound-feet of torque, especially for alternating current, are thrustor-operated. The thrustor is a hydraulic cylinder and piston, the pressure being applied by a small vertical motor and centrifugal impeller.

Band brakes are operated by a mechanism similar to that described in the foregoing paragraph and are satisfactory and desirable for many types of service if properly constructed.

For quick starting and stopping, the brake drum should be of small diameter and low inertia. The brake shoes should lift clear of the drum when the brake is released to prevent dragging. The adjustments should be few and should embody adjustment of spring pressure for braking torque, shoe clearance to compensate for wear of the lining, and an adjustment to equalize clearance of the shoes. The brake rating and setting should usually be equal to or greater (say 2.5 per cent greater) than the full-load torque of the motor. If not on the name plate, it may be computed by torque in pound-feet = 5,250 × hp (rated)/rpm (full load).

The eddy-current loading brake shown in Fig. 28-47 is a very useful magnetic device for conducting output-load tests on small machines (5 hp or less), particularly electric motors. The load may be varied over any range within the capacity of the brake in any increments desired by variation of the current in the loading coils. The aluminum disk *D* is keyed to the shaft and the rest of the brake carried on bearings *E* mounted on the shaft and supporting the torque arms *A*. The disk cuts the adjustable flux from the magnetic yokes *F*, which are energized by the loading coils *C*. The rate of cutting the flux determines the magnitude of the eddy currents formed in the disk and hence the torque released by the shaft. Power is dissipated by natural convection to the air surrounding the rotating disk. Torque in pound-feet is determined by the product of the lever arm *L* in feet and the balance reading in pounds. The rating of this brake is practically limited by the rate at which energy can be dissipated naturally from the rotating aluminum disk. Since there is no friction involved in fixing the input to the device, it cannot grab or chatter, and the operation is steady and smooth.

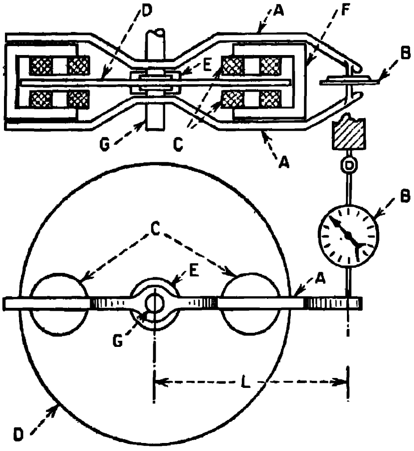

FIG. 28-47. Eddy-current loading brake.

Magnetically operated valves serve a very useful purpose and are extensively used for remote or electric control of fluid flow. They are usually of the full-on to full-off type and are seldom used for direct regulation. One example of the use in regulation would be the application to a gas-fired furnace. In this case a hand-operated throttling valve would be used to supply sufficient fuel to keep the furnace somewhat below the required operating temperature. An electrically operated auxiliary valve would supply additional fuel sufficient to exceed the operating temperature. This valve would be controlled by a temperature-actuated device and operated in an off-on manner to maintain a constant temperature in the furnace. Many manufacturers furnish valves of this character, reliable and simple in operation but with various actuating mechanisms. For large valves, or for continuous variation in throttling, motor- or thrustor-actuated valves would be used.

Magnets and solenoids are a very necessary complement to industrial plant equipment and are often a requirement for special devices. They constitute a very reliable and important device if properly constructed and applied. Their design should be developed from treatises on this subject. It should be generally understood that direct current is most desirable for the operation of tractive magnets, plunger magnets, or solenoids. This objective can often be met, when only an a-c supply is available, by means of a boundary-type rectifier such as copper oxide or selenium. A magnet should not be relied on to hold any device in a safe position. Since current supply may fail, the normal position or a latched position should be the safe one, and the magnet should be used for tripping or release.

Permanent magnets have reached such a stage in development and manufacture that the designer of modern industrial instruments and control devices would be seriously handicapped if deprived of their use. Even small motors and generators can often be constructed with a cheapness and simplicity not possible with electromagnets. Previous to 1934, the designer was dependent on carbon, tungsten, chromium, or cobalt magnet steels. The introduction of Alnico steels, composed of aluminum (Al), nickel (Ni), cobalt (Co), and iron, has given to industry a new series of permanent-magnet materials vastly superior in permanent magnetic properties to any previously existing. One in the series, Alnico 5, has an energy value twenty-five times that of 1 per cent carbon steel. At present seven steels in the Alnico series, as well as other magnetic materials, some without any iron, are available for making high-energy permanent magnets. Most of these modern magnetic materials require special casting or sintering and finishing methods. It is often better to buy the fabricated, and in many cases magnetized and finished, magnets. So many permanent magnets in various sizes and shapes have been developed that it is often possible and advantageous to adapt a stock magnet to the designer's use from the large numbers the manufacturers have available.

Any permanent magnet is subject to demagnetization from temperature changes, vibration, impact, stray magnetic fields, or contact with other magnetized materials. Modern magnets, stabilized against such influences, can be furnished by the manufacturers. The stabilized magnets are first carried to a residual induction higher than the flux density needed in the intended service and subjected to cycles of the particular demagnetizing force somewhat greater than the service will demand. This ensures a high degree of stability when the magnet is used.

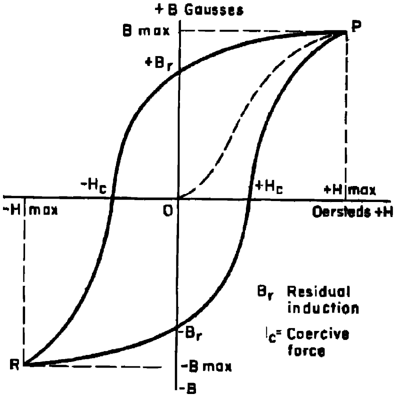

Fig. 28-48. Hysteresis curve for a permanent magnet.

Permanent magnetic properties may be discussed by the aid of Figs. 28-48 and 28-49. If any demagnetized magnetic material be magnetized by applying to it successively increased magnetizing forces H in oersteds, the flux density B in gausses will increase along such a curve as the dotted line OP, Fig. 28-48. If now the magnetizing force is decreased, the flux density will decrease, but not so fast as it previously increased, along the line PB_r. It will be observed that at 0 oersteds there still remains a flux density of B_r gausses. This is called residual induction. To reduce the flux density to zero, the magnetizing force must be reversed. As the magnetizing force is increased in a negative direction, the flux density will decrease along a line as shown, from B_r at $H = 0$ to 0 at $H = -H_c$. The value of negative magnetizing force required to reduce the flux density to zero is in magnitude H_c and is called the coercive force. Further increase of $-H$ will produce a flux density in a negative direction at point R equal in magnitude to the positive value at point P. The cycle of magnetizing forces and corresponding flux densities may be carried through the other remaining values to the point P and thus complete the hysteresis loop.

The important points to note are B_r, the residual induction, and $-H_c$, the coercive force. The corresponding values of B_r and $-H_c$ measure the external energy of the magnet, *i.e.*, represent the variation in potential energy available for external use. The section of the curve between B_r and $-H_c$ is replotted to an enlarged scale in Fig. 28-49. The products of flux density B_d at any point and the corresponding value of the demagnetizing force $-H_d$ are plotted in the curve at the right of the axis OB. This is the external energy curve. The curve signifies the flux density at which a magnet will give the maximum

energy output. To obtain a minimum volume in a magnet, the design should be such that it will operate at the flux density that makes use of the maximum external energy.

Magnetic separation for protection of equipment and foods, as well as segregation and recovery of magnetic materials, is an important application of magnetism. In many industries it is necessary to protect from damage by tramp iron (manganese steel is nonmagnetic and an exception) and foods in process from parts of machinery and tools. In mineral and mining industries, considerable segregation and concentration of unlike materials may be accomplished by taking advantage of their differences in permeability. In iron foundries, materials such as chaplets, sprues, shot iron, etc., may be recovered from molding sand. In the sugar industry, for example, the shredder or extraction rolls would be badly damaged if steel from the cane-harvesting equipment were carried along with the cane to the shredder or crushing rolls. It is also desirable to remove particles of scale or rust introduced into the syrup from the inside surfaces with which the liquid comes in contact. This material is not strongly magnetic and requires a field of high intensity for its removal. The intensity of field required for a particular application will vary with the permeability of the material that is to be separated and the depth of the load on the belt or carrier. It may often be necessary to spread the load very thinly as it passes over the magnetic separator.

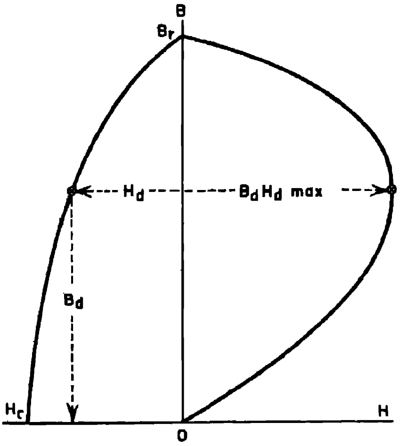

FIG. 28-49. External energy curve.

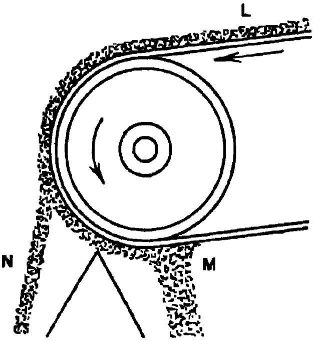

FIG. 28-50. Magnetic pulley, end view.

A device commonly used in magnetic separation is the magnetic pulley shown in end elevation in Fig. 28-50 and in longitudinal cross section in Fig. 28-51. The pulley shown in Figs. 28-50 and 28-51 is magnetic over its entire surface. The magnetic material in the conveyor load approaching the pulley at *L* is held against the pulley through the one-half circumference or so until it is removed from the magnetic influence in the neighborhood of *M*. The nonmagnetic material leaves the pulley under the action of gravity when it reaches a point where the surface of the pulley is vertical. The pulley consists of a number of magnetic poles as indicated in Fig. 28-51. The poles are created by the exciting coils *E* surrounding the core *A*, causing the flux to flow through the disks which separate the coils and form the poles. A strong field is created external to the nonmagnetic shell *D* and takes the general path indicated in *F*. Direct current for excitation of the coils is supplied through the collector rings *C*. Where only alternating current is available, direct current may be conveniently obtained by means of electronic rectifiers. It will be seen that for continuous service this pulley presents a problem in dissipating the heat generated in the coils. It is a more or less solid mass of material, often a few feet in diameter and several feet long. The cooling can be accomplished only by convection from the outer surfaces, and even this is not effective because of the usual low speed. Elimination of the cooling problem may be accomplished by making use of the newer high-energy permanent magnetic materials. At the same time the necessity for moving contact and d-c supply is removed.

The magnetic separator drum shown in Fig. 28-52 is sometimes used. The drum *D* is of nonmagnetic material and surrounds the stationary magnet *M*, which has its poles created in a manner similar to the magnetic pulley. The drum revolves constantly around the magnet, the unsorted material is delivered at *L*, the nonmagnetic material leaves at *N*, and the magnetic material is carried around on the drum to *M* where the magnetic field becomes too weak to hold the material, and it is discharged.

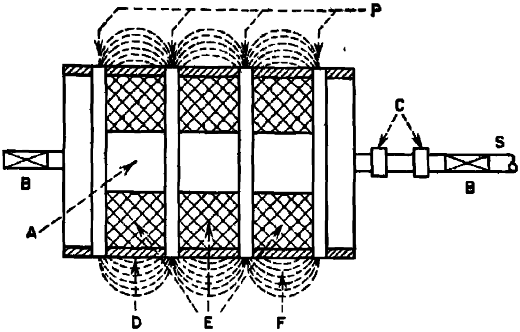

FIG. 28-51. Magnetic pulley, longitudinal section.

Another very effective magnetic separator, used for the rudimentary forms of separation, such as removing tramp iron from coal, is made by suspending a magnet similar to a lifting magnet over the conveyor belt. Since the highest flux density is at the center of this magnet, the total diameter of the magnet should be great enough for this high flux density to cover the belt width. This form of separator for iron pieces of troublesome shape entrained with large lumps gives good performance. It is also possible with this device to operate the conveyor belt at a much higher speed, 500 fpm or more, and still maintain effective separation.

A more refined type of separator is constructed by running a horizontal conveyor belt between the poles of very strong magnets with their fields vertical through the belt. The poles below the conveyor belt are broad and flat, and those above the belt are brought to a narrow edge in order that a very high-density field may be obtained. Small transverse belts move over the main belt and its load but under the concentrated pole where the high flux density exists. Magnetic material rises from the conveyor belt through the high flux density toward the narrow poles but is intercepted by the moving transverse belt and carried off to suitable chutes or collecting bins. This machine may be provided with as many pairs of poles as desired so that a mixture of materials of many permeabilities, varying from strongly magnetic to feebly magnetic, may be separated. A series of materials of decreasing susceptibility, such as magnetite, franklinite, ilmenite, cerium, manganese, pyrrhotite, palladium, strontium, biotite, and chromium, could be separated in the order given. The first-named mineral has the highest susceptibility and is removed first under a comparatively weak field. The others are removed in order as the conveyor belt carries them to stronger and stronger fields under successive pairs of poles.

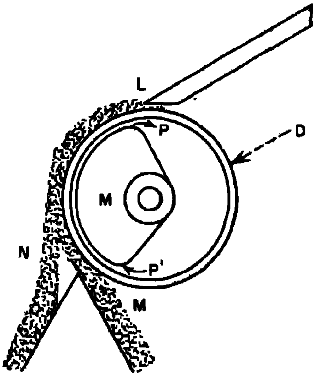

FIG. 28-52. Magnetic separator drum.

Nondestructive testing by magnetic methods has become of great importance in the manufacture and use of steel products within the past two decades. It is based on the very high reluctance of gas or other occluded nonmagnetic bodies compared with the low reluctance of the steel body in which it appears as a flaw. Of course, surface cracks, whether resulting from improper methods of heat-treating or grinding, or from other cause, fall into the same physical category. The interruption in the magnetic continuity is most evident when the flaw is at the surface, but in any case it will distort otherwise parallel flux lines as represented in Fig. 28-53. It is desirable that the flux be perpendicular to the long dimension of the defect, and this is accomplished by properly orienting the magnetizing force with respect to the defect. For example, in a steel bar or shaft where the defects are suspected of being transverse, the bar may be magnetized longitudinally by means of a solenoid that encircles it. However, defects may be longitudinal, resulting from long seams, splits, slag inclusions, or other defects rolled into the piece. For this work a heavy current through the bar from end to end will magnetize it circumferentially. On the other hand, a hollow shaft that would be likely to have longitudinal defects could be conveniently magnetized by a heavy current in a conductor threaded through the shaft. This would create a flux around the periphery of the shaft normal to the general direction of the defects. It is desirable, but not essential, that the flux be normal to the long axis of the defect; for no matter what the respective general directions of flux and flaws are, there is usually some directional component that will reveal the defect.

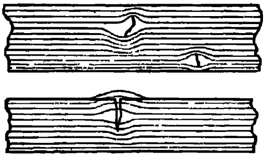

FIG. 28-53. The distortion of magnetic flux by flaws.

Methods of detecting this deviation of flux are numerous. A modified form of fluxmeter, with an exploring coil which may be moved about over the surface of the piece undergoing test, is very effective on some types of work. The presence of a fault may be indicated by a scale on an instrument scale or dial or by audible means. The audible detection is particularly useful in the form of a headphone when an a-c excitation is used in connection with an amplifier. In general, a higher flux density will be produced by direct current and more obscure faults revealed; hence its use is more general. When an alternating current is used, the necessity of subsequent demagnetization is eliminated. Detection of faults by observation of the orientation of finely divided magnetic particles was the first method employed and has been highly developed. The article under test is often immersed in an oil suspension of the magnetic particles and their orientation readily observed. The iron filings first employed were found to be most faulty as detectors. They often contained carbon and retained permanent magnetism, were not finely enough divided for exact work, and settled too rapidly for use in an oil suspension. Magnetic oxides are now available in gray, red, and black, so finely divided as to orient over minute flaws, remain in suspension in the lightest oil, as well as offer a high degree of visibility on account of the possible contrast of color that may be selected for a particular surface. The magnetic powder may be dusted on a surface from a shaker or applied in an air stream from a suitable blower. This method is often used in preference to oil immersion or when oil immersion is impracticable. A convenient detector is made by enclosing a thin layer of oil-suspended particles in a very thin, circular, highly polished, nonmagnetic tray or dish with a clear-glass or plastic cover. When this detector is moved over a magnetized surface, the particles may be seen to orient themselves about the distorted magnetic lines at a fault. This method, as well as the fluxmeter method, avoids the necessity of cleaning the article following examination.

The magnetization and demagnetization may be accomplished in numberless ways, and many special equipments have been developed for this express use. Direct current is most frequently used but is not so easy to obtain in high values as alternating current because of the ease of transformation of the latter. Direct current may be obtained from a large storage battery with cells connected for a high rate of discharge, from special high-current low-voltage generators, or from the discharge of large capacitors. Capacitors are also useful in demagnetization if connected in parallel with a magnetizing coil. When the magnetizing current is removed by opening the switch, the decaying oscillatory discharge which results will demagnetize any material threaded by the coil flux. Where the size and shape of work will permit, it may be introduced into an a-c solenoid and the current slowly decreased from its maximum value to zero. The demagnetizing coil is improved by having a laminated outer casing to limit the current inrush when its load of material to be demagnetized is small.

A fluorescent method of detecting surface cracks or flaws in nonmagnetic material, including plastics and ceramics, possesses considerable merit and will be noted here, although it is not magnetic in character. In its ultimate concepts and development it is a relatively new method of nondestructive testing. It may have been suggested by the old method of permeating surface cracks by wiping the surface with whiting and kerosene. The whiting was often carried into cracks by the kerosene and thus revealed otherwise invisible flaws. The newer method is a distinct refinement of this somewhat crude procedure. A very finely divided powder is combined with a penetrating oil to go into flaws too small to be found by the unaided eye. When the surface is illuminated by "black" or ultraviolet light, the fluorescent glow emanating from the permeated flaws is plainly visible. The object is preferably viewed in a subdued light under ultraviolet excitation of 3200 to 4000 Å. Total darkness is unnecessary, as the fluorescence emits a blue-green glow from the flaws and is readily visible except in bright light. In addition to its use on nonmagnetic materials, this method has been used to advantage on highly polished magnetic materials where the highlights interfered with high visual acuity.

ELECTRONICS

Electronics in industry has been increasing in importance since about 1932, but its applications were greatly accelerated under the influence of the demands of the Second World War. There are innumerable ways in which electronics can serve the industrial plant, and new ways are being found and used daily, but they may be grouped in five categories:

1. Tool in production processes
2. Testing and inspection
3. Instrumentation
4. Measurement
5. Protection

Electric theory and electronic principles will not be developed here because numerous texts are available dealing with these extensive subjects. Neither will a catalogue of the innumerable circuits and applications be introduced here, rather, some examples suggesting typical applications will be cited. The electron tube, or photoelectric cell, furnishes the brain of an application; and the electric circuit that it controls, the body of the creature. The electrons within the electronic tube or photocell have so little inertia that the time involved in their movement, or energy for their control, is negligible. The electron tube may be looked upon as a switch that can be completely closed in a microsecond or so and opened in a millisecond. The lever that operates this switch may be a few microamperes or less from a photoelectric cell or other detecting device. These very small amounts of energy, when properly directed and amplified, can easily control with exactitude thousands of kilowatts. In a true sense, an electronic function involves the control of free electrons. Among common examples is the action in a thermionic tube, photoelectric cell, X-ray tube, cathode-ray tube, electron microscope, gas and vapor rectifiers, and the common fluorescent lamp. High-frequency induction furnaces, dielectric heating equipment, and many other similar devices are also classed as electronic, since, though not strictly electronic, they are closely associated with the electronic domain.

Induction heating was recognized as practicable by many scientists and engineers as early as 1890, but it was 25 years later before extensive use was made of the process. The melting of metals for the manufacture of ingots of brass, bronze, nickel-silver, jeweler's metal, etc., in this country is nearly all done by the low-frequency or core-type induction furnace. This furnace is essentially a core-type transformer where the primary coil is connected to a source of commercial frequency, and the secondary consists of a ring or single turn formed of the metal that is to be melted. In the early furnaces this ring was horizontal, but this form of furnace—largely because of the troublesome pinch effect—was abandoned in favor of the vertical-ring type represented by the Ajax-Wyatt furnace. A diagram of this furnace without the structural details, supporting frame, etc., is given in Fig. 28-54. The ring of metal in the V-shaped channel *E* is completed by the reservoir *A*. The laminated core *D* is magnetized by the primary winding *C*. The body of the furnace *F* is constructed of refractory insulating and supporting materials. The molten metal is rapidly stirred by the electrodynamic forces in the V-shaped channel *E*, and this rapid movement carries on into the reservoir *A*, as indicated by the dotted line near *B*. The most common size of furnace has a capacity of some 900 to 1,000 lb of metal, and from 600 to 750 lb is tapped at each heat, the balance being retained in the furnace to preserve the closed ring in the channel. When started, the furnace is filled with molten metal and must be entirely emptied or kept running at reduced energy input when production is interrupted. Heats can be run off quickly, the furnace has a low energy consumption under continuous production, and the power factor approximates 75 per cent.

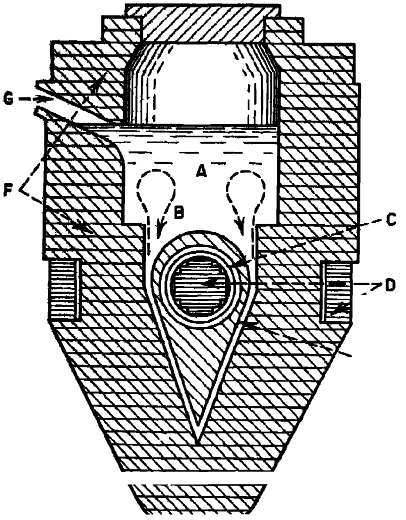

Fig. 28-54. Vertical-ring low-frequency induction furnace.

The high-frequency induction furnace has been developed since the low-frequency one proved so successful. The charge in this furnace is also the secondary of a transformer which operates without a core, and this furnace is frequently called the coreless induction furnace. In Fig. 28-55, a charge of conducting material *A* is contained in a refractory lining or crucible *B*. The charge is cut by a high-frequency electromagnetic flux supplied by the single-layer exciting coil *C*. This coil is usually made from round copper tubing that has been partially flattened to the approximate cross section of an ellipse, through which water flows to carry away the heat and reduce its resistance losses. It is commonly made with the height about equal to the diameter, but it may vary more or less from this proportion. The heating of the charge is by induction from the action of eddy currents, and hysteresis in the case of magnetic materials when below the recalescence point in temperature. (Nonconducting materials are often melted by placing them in a conducting crucible, such as graphite.)

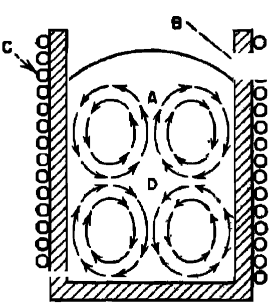

Fig. 28-55. Coreless or high-frequency induction furnace, elementary arrangement.

The depth of penetration is governed by the resistivity of the material and frequency of the flux. It is expressed by the formula $\delta = 5{,}030\sqrt{\rho/f}$, where δ is the equivalent depth of penetration in centimeters when uniform current over the shell of δ-cm depth is assumed; ρ, the resistivity of the material in ohms per centimeter cube; and f, the frequency in cycles per second. The effective resistance R_e equals $\delta 2\pi(a - \delta/2)/\delta l$ (ohms), where a is the average outside radius of the charge and l its axial length. The effective reactance X_e equals $2\pi a\rho N^2/\delta l + (8\pi^3 f N^2/l)(b^2 - a^2)10^{-9}$ (ohms), where b is the average radius of the primary coil and N is the number of turns in the primary. From these formulas the electrical characteristics of a coreless induction melting furnace may readily be computed.

The equivalent circuit of the coreless induction furnace is indicated in Fig. 28-56. As is usual, the primary and secondary parameters may be combined to form equivalent resistance, reactance, and impedance referred to the primary side. For commercial furnaces with capacities from a few hundred pounds to a few tons, power at frequencies of 960 or 480 cps is used and is obtained from specially built synchronous generators. In order that a good power output of the generator may be obtained without excessive heating, power-factor-correcting capacitors are applied to the furnace circuit as indicated in Fig. 28-57, where *A-A* represents the primary coil of the furnace with taps for adjusting the voltage. It may thus be used as an autotransformer for adjusting the voltage on the capacitors, thereby adding flexibility to the arrangement.

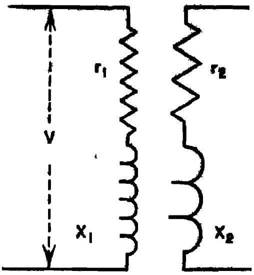

Fig. 28-56. Equivalent circuit of coreless induction furnace.

Smaller high-frequency induction furnaces for laboratory use or for commercial melting of a few ounces or pounds of precious or high-melting-point metals use frequencies of 10,000 or 20,000 or more cps. The generator for this use consists of a steel-core transformer with a relatively high leakage reactance. The primary winding *P-P* (Fig. 28-58) is connected to a supply line of commercial frequency. A high-voltage secondary *S-S* is connected to the inductive coil of the furnace *F-F* through the capacitors *C′* and *C″*. This will be recognized as an oscillatory circuit. The hydrogen-quenched mercury spark gap *G* is connected across the high-voltage terminals of the transformer. When the voltage across the transformer reaches a critical value, a breakdown and spark discharge occurs, and the ensuing oscillation furnishes the necessary frequency of several thousand cycles per second. Each alternation of the primary voltage initiates a new oscillatory discharge, thus maintaining the high-frequency supply. The same principles discussed in connection with the synchronous-generator-operated furnace apply to the oscillator-operated furnaces, except that the frequency and wave form are neither fixed nor constant.

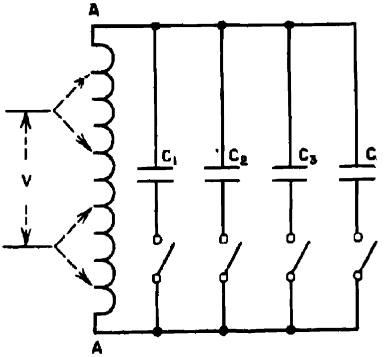

Fig. 28-57. Circuit arrangement for power-factor correction of coreless induction furnace.

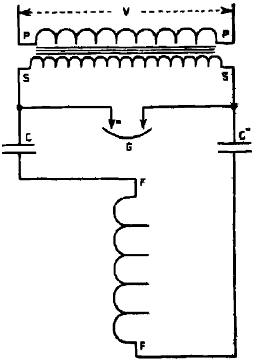

Fig. 28-58. Circuit arrangement for small high-frequency induction furnace.

Radio-frequency induction heating started about 1925. The automobile industry needed parts with a hard surface to resist wear and a tough core with better mechanical properties than could be had by casehardening mild steel. This was accomplished by subjecting the parts to an alternating flux of so high a frequency that there was very little depth to its penetration and then quenching the part to produce the hard surface. When cold ferrous metals are subjected to radio frequency, the permeability

—which is of a high value since the metal is far below the point of recalescence—must be considered. This requires that permeability be introduced into the denominator of the radical in the penetration formula. It will be evident, then, that the depth of heating may be kept as close to the surface as desired or increased by proper control of frequency and time. A short-time heating does not allow heat penetration by heat conduction.

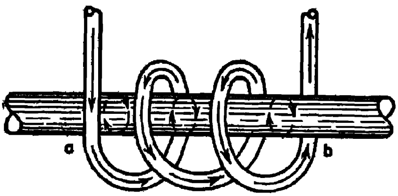

FIG. 28-59. Heating the middle of a bar by high-frequency induction.

If a gear, for example, is to have a tough strong center which will resist shock, yet have the surface of the teeth hard enough to resist wear, the result may be achieved by quickly heating the object in an induction heating coil and quenching it instantly *in situ*. This is readily accomplished by doing the heating in a basin that may be instantly flooded with quenching fluid and as quickly emptied. The basin is ready for the next workpiece as soon as it is emptied, which results in very rapid heat-treating with the rapidity limited mainly by the very short heating period. Very rapid brazing of parts may also be accomplished by high-frequency induction heating. If a flat surface is to be heated, this is effectively accomplished by means of a pancake coil adjacent to the surface. Three representative conditions are indicated in Figs. 28-59, 28-60, and 28-61. In Fig. 28-59, a bar is introduced into a coil of a few turns and heated only in the region *ab*, which is cut by the flux of the coil. The remainder of the bar will receive heat only by conduction from the heated region, even though this region is at a bright orange heat. The bar may be heated in a few seconds, and the short time allowed for conduction of heat along the bar is one of the strong advantages of this method of heating. In Fig. 28-60, the end of a chisel is introduced into a coil, and only the end within the coil for heating to a hardening temperature will be acted on by the coil flux. A flat block is adjacent to a pancake coil in Fig. 28-61, and only the face of the block nearest the coil will have any great amount of heat developed in it. Such examples, given as illustrations of the method of selective heating, could be repeated indefinitely. The configurations of the fields and eddy-current paths are so obscure and complicated that it is difficult to predict by computation just what heating results will be achieved with a given coil, frequency, and object. The variation of frequency and construction of a coil are so simple, however, that a trial can be made in a fraction of the time that would be used in an attempted calculation. Once the frequency and coil construction are established, however, the heating process can be repeated with exactitude.

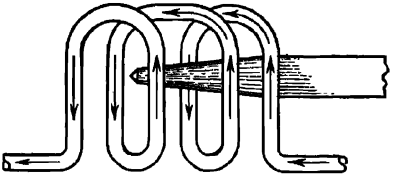

FIG. 28-60. Heating the end of a bar by high-frequency induction.

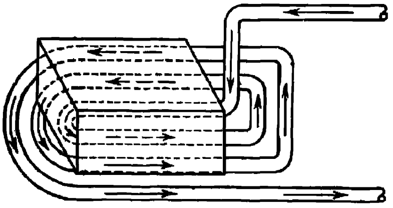

FIG. 28-61. Heating the flat surface of a block by high-frequency induction.

Dielectric heating is sometimes called "electrostatic" heating. This is an error. Static electricity is stationary and, of course, can produce no heating effect. A capacitor, such as is used for power-factor improvement, consists essentially of two conducting plates separated by a dielectric. There is a small amount of heating in the dielectric of the condenser when the plates are energized by an alternating current of low frequency.

The heating is considered to be due to dielectric hysteresis, which has a characteristic similar to magnetic hysteresis, and also to the Joule effect of the current flowing through it. The quotient of this loss expressed in watts and the volt-amperes delivered to the terminals is the power factor of the capacitor. As the frequency of the applied voltage is increased, the impedance of the capacitor decreases in the inverse sense, or with a fixed voltage, the current increases directly with the frequency. The heating is also dependent on the dielectric constant of the material.

If a dielectric fills the space between two flat plates and the edge effect is neglected, the frequency used will depend upon the characteristics of the material, *i.e.*, the power factor, dielectric constant, and the loss factor at the frequency at which the material is to be heated. The power absorbed is approximately

$$P = 1.41 \times 10^{-12} f V^2 \lambda K A / d \qquad \text{watts}$$

where f = frequency, cps
V = rms voltage
λ = power factor
K = dielectric constant
A = area, sq in.
d = thickness of the work, in.

The heating energy in watthours is

$$W = wc\Delta T 10^3/0.95$$

where w = weight of dielectric heated, lb
c = specific heat
ΔT = temperature rise, deg F

By making use of the foregoing formulas, the heating of a dielectric may be closely approximated. However, the following points should be noted: (1) the power factor of the material at the operating temperature and frequency should be known; (2) the dielectric constant does not change greatly with temperature, and if the value at room temperature is used, the results will be as precise as the remainder of the computation warrants; (3) no allowance is made for edge effect, and it is also assumed that the thickness of the dielectric is small compared with its width; (4) for most materials, voltages should not exceed 3 kv per in.; (5) a total voltage in excess of 20 or 25 kv will result in troublesome corona and arcing. At present the available equipment limits the frequency to about 200 megacycles for power output up to 100 watts; to 30 megacycles for power to 40 kw; and to 4 megacycles for greater power outputs. To avoid nonuniform heating from standing waves, the maximum dimensions of an electrode should not exceed one-eighth the wave length used. The wave length in meters is $l = 3 \times 10^8/f$ in a vacuum and substantially the same in air. Air gaps between the electrodes and the material introduce a series capacitance and will introduce large errors in the estimates. Solid dielectrics usually have dielectric constants between 2 and 8.

Rectification of alternating current is by far the most extensive use of electronics when total energy controlled is the criterion. Transformers to change the voltage and tube or steel-tank rectifiers to convert the current to direct provide flexible and efficient apparatus with no moving parts with relatively low investment costs. More than 10 per cent of the total energy used in the United States at the present time flows through rectifiers before use. The magnitude of current conversion extends from a few microamperes to supply a positive potential to the plate of an amplifier tube to many thousands of amperes—furnished by mercury-pool steel-tank rectifiers—to equipment for the electrolytic reduction of aluminum or magnesium. The mechanism of rectification is the same in either case. It results from the physical circumstance that electrons or negative ions will flow freely from a cathode which is maintained negative to an anode which is maintained positive and will not flow in the opposite direction so long as the inverse voltage is kept below a certain critical value, the inverse-voltage rating of the device in use. In the tube, conduction is established by electrons emitted from the hot filament (thermionic emission); in the mercury-arc rectifier, conduction is established by the release of negative ions from the mercury surface to the arc stream by a very high voltage gradient at the surface of the mercury. The electronic or ionic conduction is maintained on the same basis: movement of the negatively charged bodies in a particular direction, *i.e.*, positive, in an electric field. The rectifier thus supplied is necessary for a variety of d-c applications where process control, electrical, mechanical, or optical measurements, or alarms and safeguards are required. The most extensive use is in the millions of kilowatts of installed capacity for aluminum and magnesium reduction. Much additional use is for d-c railways; d-c power for adjustable- and variable-speed machine drives; auxiliary drives for hoists, cranes, ore bridges, coke ovens, and blast furnaces; as well as extensive use on main drives in steel mills. The mining industry makes use of this equipment to supply direct current to mine haulage systems, coal-cutting and ore-loading equipment. Battery-charging equipment for any battery can be secured.

The adjustable-speed electronic drive for d-c motors provides, in one device energized from an a-c supply line, starting and accelerating with control of speed and torque. Figure 28-62 is a schematic diagram of the arrangement. The electron tubes convert alternating current from the transformer into direct current which is supplied and controlled independently for armature and field. The instantaneous response of the tubes provides constant and precise control of speed and torque by control of both armature and field current. Compensation for armature *IR* drop aids in maintaining constant speed independent of load, and armature control in conjunction with field control provides for a very wide speed adjustment. Constant-current acceleration is also provided, and the current and torque peaks that would result from step-by-step acceleration are eliminated.

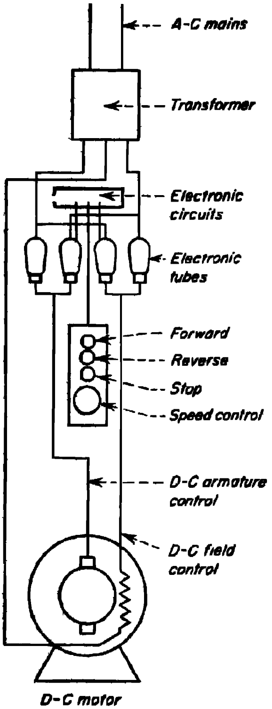

FIG. 28-62. General arrangement of electronic operation of adjustable-speed drive.

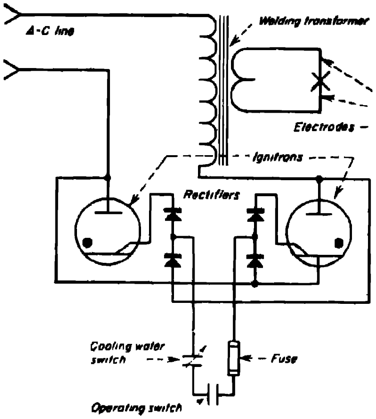

FIG. 28-63. Electronic control of resistance welding.

Resistance welding control is one of the most important contributions of electronic control to industrial applications. Electric resistance welding is the only method of metal fabrication that adds no weight or additional parts to the structure, and it provides consistent quality in the junctions with fewer handling operations It is adaptable to sheets from a few millionths of an inch to ½ in. or more in thickness. In the control of this work, ignitrons controlled by thyratrons provide instantaneous switching with practically perfect timing or spacing of welds without noise or vibration. Control of the magnitude of the current provides adjustment of heat without tap changing. Synchronous switching by thyratron control allows adjustment of time and current control for each weld, with increased speed of welding, improved quality of weld, and greatly increased life of the welding machine. The very narrow range of temperature for the plastic state of most nonferrous metals made the development of the energy-storage system of welding desirable. In this system, a-c energy is converted to d-c energy and intermittently stored in capacitors or inductors, then quickly discharged through the welding transformer. The slow storage and quick discharge of the energy, together with the distribution of the load over three phases, greatly reduce the kva demand on welder supply systems. Electronic control is highly flexible and readily adapted to local needs and plant conditions. Figure 28-63 is a typical circuit arrangement for a resistance welder.

Electronic timing, aside from the timing of resistance welding previously noted, is very widely used in industry; it is accurate, reliable, and readily adjustable. If a potential E is applied to a capacitance C and resistance R connected in series, the value of the current i at a time t sec after the voltage is applied is fixed by the following relation:

$$i = (E/R)\epsilon^{-t/RC}$$

where $\epsilon = 2.718+$ is the base of the natural logarithms. The time constant is RC in seconds with E in volts, i in amperes, C in farads, and R in ohms. If the resistor and capacitor are connected in parallel, the relation is

$$i = -(E/R)\epsilon^{-t/RC}$$

An inductor of L henries could also be used, and if connected in series with a resistor the relation of the quantities is

$$i = (E/R)(1 - \epsilon^{-Rt/L})$$

If the inductance and resistance are connected in parallel, the relation is

$$i = -(E/R)\epsilon^{-Rt/L}$$

The time constant for the inductive cases is L/R. The foregoing relations form the basis of electronic timing. It will be observed that with a fixed voltage and inductance, or capacitance, the resistor can be varied in value to cause the current to reach any selected value in a predetermined time. By proper choice of the circuit and its parameters, the time taken for the voltage across capacitor, resistor, or inductor to reach a desired value is subject to definite adjustment.

The timing device described may be connected so that the voltage across any element of it may be applied to the grid of an electronic tube, and the voltage so selected that the tube is rendered conducting or nonconducting at a predetermined time. This combination represents a timing relay and may be combined with more powerful devices to meet almost any industrial timing need, whether it be milliseconds, seconds, or even several minutes. It is used for timing plastic molding—the various divisions of press-operating cycles in injection moulding, for example—and is generally used for any machine-operating sequences that can be controlled by electrical or electromechanical means.

Temperature control is also readily accomplished by electronic means. This may be particularly simple and direct in the case of electric resistance heating. One useful method consists in supplying the heating load through a main winding of a two-winding iron-core reactor. This winding has a low resistance and, when the core is unsaturated, a considerable reactance. Of course the reactance will be greatly reduced if the core is saturated by means of a direct current in the auxiliary winding. This suggests the electronic control of a-c resistance heating. The furnace or oven windings are fed with a saturable-core reactor in series. A control panel embodies a rectifier to supply direct current for the reactor auxiliary winding and an electronic means of increasing or decreasing this current to adjust the furnace temperature in response to a thermocouple or other temperature detector. The elements embodied in this method of regulation are indicated in Fig. 28-64. This regulating method is suited to a great variety of processes suggested by heat-treating of all kinds, vulcanizing, strip annealing, glass lehrs, air heaters, etc.

Regulating applications of electronics are numberless, particularly speed regulating and voltage control. Most controls of this character involve the elementary system indicated in Fig. 28-65. In this system a piece of equipment, often very large, is to be controlled to meet a definite condition set by a reference standard. This standard and some small detecting device actuated by the main equipment feed a signal into a balance detector. This signal generally represents the difference between the standard quantity and a quantity represented by the operating condition of the main device. The balance detector determines the unbalance between the detecting device and the standard and supplies a corresponding signal to the controller. The controller then acts on the main equipment to reduce the variation between its operating condition and the standard condition represented by the reference standard. It thus effects the operation of the main equipment under preselected conditions.

An example of the foregoing control is the paper-machine drive. In this machine several machines must be coordinated, each performing a separate function on a continuous web of paper which changes in length as it passes through the machines, and must have their various speeds adjusted to accommodate them to the change in length. Furthermore, the web starts as a mixture of ½ per cent cellulose suspended in a matrix of water, travels at a speed between 300 and 1,500 fpm, and must result in a finished roll of paper of the required size between 0.00025 and 0.040 in. thick. While traveling at its normal speed the water is removed and the paper dried, sized, calendered, and reeled. Each separate machine has its own pilot generator driven from the driving motor of the machine. The voltage of the pilot generator is matched against a reference voltage and the difference applied to the grid of an electron tube. This signal acts to control the motor field—and hence its speed—through an electronic amplifier and an amplidyne exciter. This is but one example of numerous controls, extending from the lightest to the heaviest machinery, that are becoming increasingly common but precise in their action.

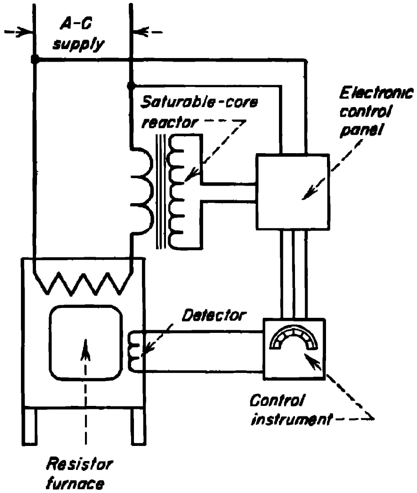

FIG. 28-64. Automatic temperature control in resistance furnace by saturable-core reactor.

The photoelectric cell, from its beginning as a control for the familiar door-opening device, has become one of the most useful electric tools of the century. It receives its excitation from a light source by direct radiation, by reflected light, by transmitted light, or by refracted light. This light impinging on the photocell sets free, by photoemission, electrons which become a current—usually of a few microamperes—which initiates the desired control, sounds a warning, opens or closes, counts, diverts, discards, limits, protects, selects, matches, or does any of thousands of things that it can do better and with vastly greater speed than can the human eye. A very few applications will be mentioned here as representative. Any large manufacturer of photoelectric-control equipment can supply lists of hundreds of successful applications of this tool so extensively used that it has long since ceased to be new.

One of the early applications of the photocell was to initiate movement by the obstruction of a light beam. As long as the beam of light shone on the photocell, its stream of electrons through a resistor would prevent the grid of an electron tube from becoming negative. An interception of the beam would remove the positive voltage, allow the grid to swing to negative, the tube to conduct, and, for example, the door to open. Another early representative use was for burglar protection. A labyrinth of beams of invisible ultraviolet or infrared light could be reflected between mirrors and ultimately reach a photocell. With any interruption in this multiple beam, the conduction of the controlled tubes would fail, and an audible or visual signal would be given. Innumerable assemblies, both standard and special, for sabotage fences were used during the war, and many were arranged to photograph the intruder automatically. When smoke intercepts the beam, a measurement of the density of the smoke may be made and recorded as an aid in smoke control. The same principles apply to turbidity control for giving a warning when a water supply is contaminated or automatically diverting the supply that has entrained sediment. It is also useful in the automatic supervision of chlorination, in filtering, determining hydrogen-ion concentrations, titration, indication of sludge level, and in innumerable applications where the partial or total interception of a beam of light will convey the needed information.

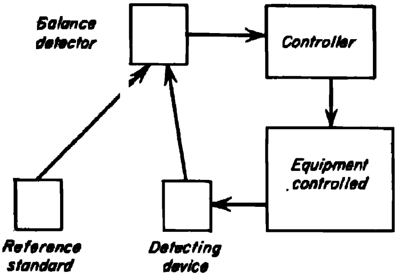

FIG. 28-65. Scheme for electronically matching performance of equipment with a reference standard.

Pinholes in metal or other opaque sheets are automatically detected by photoelectric cells and the defective sheet marked or diverted. Many plants also use machines that sort the sheets for thickness, count, and pile them, all by electronic means. Tons of beans are sorted and any discolored bean rejected into the chute for discards. Traffic-control equipment sorts traffic as readily as the bean sorter sorts beans. A vehicle of excessive height, or one carrying a load that projects too high, signals its condition to the traffic officer on duty, and if it is not immediately halted, the traffic light is changed to red. Traffic is often regulated in tunnels by devices that count the number of vehicles entering the tunnel and the number leaving. The difference represents the number of vehicles in the tunnel. Any excess over a preset number causes a red traffic light to show. At the same time, more ventilating fans are started. Of course this same scheme is applied to the movement of smaller and less cumbersome articles. The number of cars passing over a highway, as well as their speed, is often recorded by photoelectric equipment and the information thus secured used as a basis for traffic regulation and highway development.

The human eye, at best, can detect perhaps 10,000 colors and shades. The spectrophotometer, an instrument combining suitable filters and photoelectric cells, can differentiate between more than 2 million colors, hues, and shades and record them as certain curves or represent them as wave-length numbers in the visible spectrum. The information represents the reflectance of each different wave length by the sample as measured by the instrument. By this means two pieces of cloth manufactured in widely differing localities can be made to match perfectly. A banana ripened in Boston could, by proper control of temperature and humidity, be ripened to match a similar one in New Orleans. This instrument is invaluable in many applications in the medical, pharmaceutical, metallurgical, and chemical fields where delicate color changes are to be studied quantitatively.

The photoelectric cell may be used as an important device for aiding in temperature determination and control when the range is of the order where radiation pyrometry is useful. The improvement in uniformity and quality and decrease in spoilage of product of many steel mills have been marked by its use. A photoelectric pyrometer located to "look at" the center of the section of a bloom or bar in process may be interlocked with controllers in the pulpit, ensuring a finishing at the best rolling temperature. The photoelectric cell may watch the flame of a Bessemer converter through specially selected filters, record the progress of the blow, and catch the end point of the blow at exactly the preselected instant. In centrifugal casting the photocell watches the inside of the spinning pipe or tube as it cools and causes the driving motor to stop at the critical temperature. This enables the maximum use to be made of the casting machine, with a corresponding increase in output. In portland-cement manufacture, control of clinker temperature has increased the output per kiln, lowered fuel cost per barrel of cement, and produced cement of better and more uniform quality. The control is complete and automatic. A suitable optical system focuses the hottest part of the clinker bed on the photoelectric cell, and the speed of rotation is changed to maintain a constant clinker temperature. Temperature and kiln speed are also simultaneously recorded. A legion of photoelectric controls is suggested by these diverse applications, which are intended to suggest applicability rather than to be guides to practice.

Photoelectric positioning control brings scientific assurance that a piece of printed paper, a strip of steel, a web of cloth, a packaging container, or a power shovel weighing more than 1,000 tons will be in the proper position at precisely the right time. Weft straighteners, for squaring the weft with the warp in cloth, operate by light transmitted through the cloth to impinge on phototubes. When threads are square, the frequencies of light impulses to the tubes are equal; when skewed, are unequal. Electronic controls operate straightening mechanisms in the tentering machine to make proper corrections. Cloth speeds may range from 20 to 150 yd per min and from 20 to 100 picks per in. Side controls on steel strip reels furnish a control that produces smooth ends on the coil.

Another important device is represented by the automatic loop control applicable to all kinds of moving webs, whether light materials such as paper or cloth or heavy materials such as steel or brass strips. Figure 28-66 indicates the elements of this important control. The motor-driven rolls move the strip under control of the photoelectric cells through the amplifier and thyratron. When the loop of the strip intercepts about one-half the light from the source, the strip is in equilibrium. Any increase or decrease in the amount of light reaching the photoelectric cells acts through the amplifier and the thyratrons to change the field of the motor in such a direction as to restore equilibrium in speed.

Photoelectric control of registry is an extensive field of application and embraces such tasks as registry of postage stamps for perforating and cutting into sheets. The registry of four or more colors in turning out millions of copies of colored pictures, such as magazine covers, is accomplished by means of photoelectric register control. Each color must be printed directly on top of another within an accuracy of a few thousandths of an inch to avoid spoilage of the picture. An early application of photoelectric register is the proper location of the wrapper on candy bars or bread, for example, with respect to the object to be wrapped. This is done by making use of the pattern printed on the wrapper or by means of special registry marks printed on the wrapper. In many elevators the leveling of the car at the landings is done by photoelectric tubes mounted on the car and light sources mounted in the shaftway.

Elevator safety is often promoted by making it impossible to move a car when any part of a passenger's body extends into the doorway. This is easily accomplished by means of photoelectric relay control reacting to any obstruction of a light beam passing across the doorway. Injury to operators of dangerous machines is prevented by making it impossible for the machine to move when any part of an operator's person is in a dangerous position with respect to the machine.

Lighting control by photoelectric means is extensively practiced. When the daylight falls below a selected level in factories, offices, or schools, owing to the sun going down or to storm clouds passing over, the controls automatically turn on the lights. When the daylight returns to the proper level, the artificial lights are turned off. In installations of this character the method just described protects the worker's eye muscles from serious strain and fatigue. In stage and theater lighting where colors of light are presented in various combinations of contrast, harmony, and intensity, electronic control introduces features of regulation that are impossible by other means. The saturable reactor for changing light intensity and thyratrons or other highly conducting tubes are combined to be controlled by small buttons or keys or even by photoelectric cells with amplifiers. This permits the increase and decrease, the blending and resolution, of vast numbers of lighting combinations over extended areas with no more fingertip action than in the playing of a musical instrument. This control combination is used in many installations of decorative lighting of interiors or exteriors of buildings to enhance the architectural beauty. It is also used in the blending of rainbow colors in combinations of light that play on rising and falling water in fountains and pools.

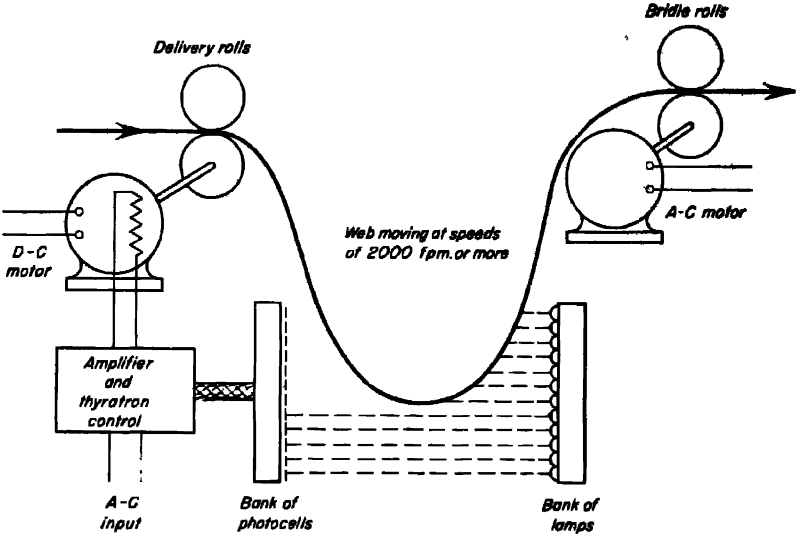

FIG. 28-66. Automatic control of a loop by electronic means.

Electrostatics play an important part in industry where control of the movement of small particles is necessary. Its most extensive application is in electrostatic precipitation and air cleaning. High voltage from transformers (usually of the order of 50,000 volts) is rectified by kenetrons or other high-vacuum-, hot-cathode-type tubes. When an electric charge is imparted to the particles of smoke or dust entrained in a gas and the gas subsequently conducted through the strong electric field existing between plates, the field impels the particles to the plates of opposite potential where they collect. The plates are then vibrated by mechanical means, and the collected particles fall into bins to be disposed of later without the need of shutting down any equipment. The foregoing is a description of the Cottrell method of precipitation. This process is widely used in the recovery of valuable materials, as well as for decontaminating air and other gases. Particles of copper carried out of copper converters in the flue dust during the blowing process are recovered by electric precipitation. Valuable arsenic dust from ore refining is recovered to prevent its settling on surrounding territory in the neighborhood, with the incidental advantage that the value of the recovered product soon pays for the precipitating equipment. Cement dust with a high potash content recovered from cement-kiln gases had a higher value per pound than the cement.

Electrocoating of many materials results in products unattainable by other means. An important example is the manufacture of high-grade abrasive papers and cloths. The arrangement is shown in Fig. 28-67. A backing coated with glue is fed into an electric field, from left to right in the top of the figure. On the bottom rolls a conveyor belt travels in the same direction. It receives grains of abrasive from a hopper which releases them in proper quantity. As they are carried into the electrostatic field they first stand on end with their longitudinal axes parallel to the field. They then fly upward along the field and are embedded in the glue with their long axes still parallel with the field. Since the particles all carry like charges, they are uniformly distributed over the surface with their sharp points outward. This results in an abrasive sheet that cuts much faster and more freely and lasts longer without loading with the abraded material than abrasive sheets with ordinary coating. If greater spacing between grains is desired—an open-coat abrasive—the rate of feed is decreased, and the electric charge evenly distributes the smaller quantity with the same uniformity.

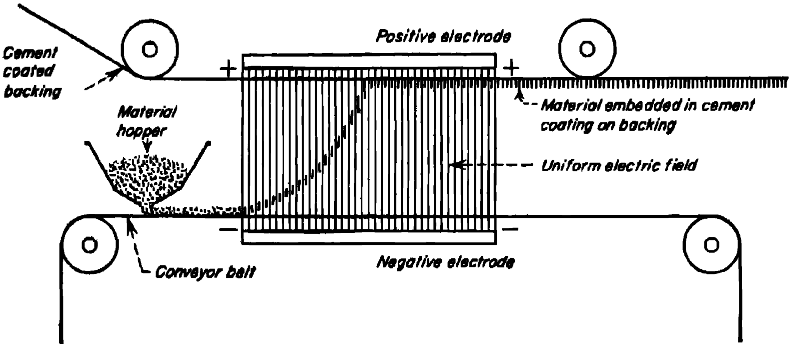

FIG. 28-67. Electrocoating in a high-intensity electric field.

The foregoing principles are made use of in the manufacture of many textile products. Flock materials are made by cementing cotton linters to a cloth or paper backing. Some 250,000 to 300,000 fibers per sq in. (over 500 per lineal in.) can be applied as compared to about 30 per cent of this number (150 per lineal in.) by weaving methods. The flock cloth may be made to resemble suede leather in surface appearance and feel. Other fabrics are produced by the use of longer fibers and resemble plush cloth and long-fibered rugs and carpets. Patterns are also produced by printing the design on the cloth in cement, in which case the fibers adhere to the printed design. The electrocoating process will expand greatly in the future, presenting many possibilities in upholstery and side-wall coverings and in the shoe and pocketbook trade, as well as in floor coverings.

MECHANICAL VIBRATION

Vibration engineering, an extensive and rapidly expanding field, involves many problems in isolation and absorption of mechanical vibrations. Some degree of unbalance is taken to be inherent in nearly all moving machinery, and the forces set up by this unbalance produce varying degrees of vibration and noise. In some degree this reduces the effectiveness of the machine and the efficiency of the employees in the neighborhood and shortens the life of the neighboring structures and equipment. Vibration is transmitted to the neighboring structures mainly by convection, the noise principally by radiation. Best machine design reduces vibration at its source but seldom eliminates it. Static balance is not sufficient to eliminate vibration; complete dynamic balance must be achieved, and this is not possible. A shaft of a machine may not possess uniform stiffness, or the field of a motor may be improperly distributed; a correction of vibration from these causes must be made when the machine is built. The seriousness of vibration effects depends upon their amplitude and frequency; and so far as human response is concerned, curves have been constructed from tests that indicate the tolerable frequencies at varying amplitudes.

The isolation, neutralization, or absorption of the vibration is often the only means of relief. Isolation is accomplished by elastic suspension, with or without damping. Although an isolated system possesses 6 deg of freedom, only motion in the direction of the principal disturbing force is considered in the solution of a vibration problem. In treating vibration troubles, several principles should be followed. The center of gravity of the isolated structure should be as nearly midway between the supports as possible; mounts should have the same static deflection; the center of gravity of the isolated structure should be as low as possible to improve stability (links may be necessary to achieve stability); where large masses and heavy impacts are involved, the center of gravity should preferably be below the supports.

So many unknowns enter into calculations of vibration isolation that results are not uniformly satisfactory. Damping coefficients are difficult to evaluate. Metal springs are easiest to calculate because of their small damping effect. A floor is often considered rigid but may in reality often contribute one of the masses and a restoring force of a two-mass system. Auxiliary devices for vibration damping are often employed, such as dashpots or other fluid damping devices used on automobiles. Friction dampers, such as those used on the crankshafts of automobile engines, are used. A cast-iron crankshaft may sometimes be used to advantage because of its internal damping due to the greater hysteresis of cast iron compared with that of steel. In the general case encountered, experience will reduce the amount of cut-and-try method necessary to solve a problem.

In commercial suspensions, metal springs will meet a wide range of vibration conditions. This is because a large variation in deflection may be had by changes in dimensions or material. Springs have the best stability when the working height is 1 to 1.5 times the diameter. Springs are not subject to damage from oil or temperature. If a spring suspension is found to transmit an excessive amount of sound, a layer of rubber, cork, or felt may be interposed.

Rubber mountings with the rubber bonded to the metal are extensively used with effective results. When used in compression, rubber will carry heavy loads, but allowance for the flow of the rubber must be made in designing the supports. When used in tension it is softer than when used in compression but is unreliable because of its weakness when abraided or nicked. Rubber is a very satisfactory material when loaded in shear, is also softer and more yielding than when used in tension or compression, and furthermore follows Hooke's law approximately when moderately loaded. It is especially useful in isolating the high frequencies of sound when through-metal is avoided in the supports. It is not so suitable as springs for isolating low frequencies. Oil and temperatures above 150°F deteriorate natural rubber, but under good conditions it should be serviceable for 5 or 10 years. Synthetic rubber stands oil and elevated temperatures better but loses its resiliency sooner.

Cork was one of the first materials used for isolation of vibration. Ground cork bonded into large slabs is a material having uniform structure and properties. Control by the bonding permits several densities for varying applications, and the deflection varies inversely as the density. It is also a good material for acoustical isolation, but through-metal must be avoided. It is particularly satisfactory for placing under a large mass and serves well when the machine is bolted to a large concrete block and the whole assembly placed on cork.

Hair felt is another material that has good properties for small deflections and high frequencies. Hence it is also a good material to limit sound transmission. The loading on large pads is usually limited to 50 psi, but on small confined pads it is sometimes used under greater pressures.

For sound and noise, screens and filters are frequently employed. An example of a screen would be a wall of sound-absorbing material interposed between the cause of the noise and the space to be quieted. An example of a filter would be the muffler for an automobile-engine exhaust. Large ducts are made, following the same principles. In such passages, free flow must be allowed in order to prevent excessive back pressure.

Vibration instruments responding to frequency, displacement, velocity, acceleration, or wave form may be necessary in the study of vibration problems. The most common need is a knowledge of frequency. Very low frequencies may often be counted by observation or by mechanical or electrical counters. For higher frequencies, vibrating-reed tachometers are useful. Various forms of stroboscopic instruments may also be used. Amplitudes of large displacements at low frequencies may be observed directly, or records of them made by means of a stylus attached to the vibrating member either with or without an amplifying system. Small vibrations of relatively higher frequencies are the more usual type and may be conveniently and completely studied by means of electrical instruments. A coil moving in a magnetic field is the commonest and most versatile device for this instrument. Its response may be shown on an oscilloscope or recorded on an oscillograph. Since the voltage produced by the movement of a coil in a uniform field is proportional to the velocity of the moving coil, a single integration of the velocity will indicate the displacement or a derivative—the acceleration.

SONICS AND ULTRASONICS

Sound Generators. The human ear can pick up sound with frequencies from about 16 to 20,000 cps, the upper limit often decreasing with increasing age. Ultrasonic frequencies are those above the audible range.

There are three general types of sound generators in commercial use, two using electric energy as the source of power and the other using compressed air. The *piezoelectric* generator employs a crystal, *e.g.*, quartz or Rochelle-salt, through which is passed a high-frequency alternating current. The crystal expands and contracts at signal frequency, generating sound waves. At the present time (1950) commercial equipment using this principle could probably be built to deliver in the order of 500 kw output. The *magnetostriction* generator employs a metal tube, bar, or laminated rod (nickel gives good results) inside a coil of wire through which is passed a high-frequency alternating current. The tube, bar, or rod expands and contracts in the resulting alternating magnetic field, and when attached to a metal diaphragm, high-frequency sound waves are produced at twice the signal frequency unless a polarizing current is applied. A machine using *compressed air*, similar to a siren, has been built which operates over a frequency range of 1,000 to 200,000 cps with intensities from about 100 to 170 db. Between 50 and 70 per cent of the energy in the compressed air is converted to sound energy.

Sonic vibrations produced by sonic oscillators are made use of in industrial processes to an increasing extent as their potentialities are recognized. One example is the application to the homogenizing of the fat and curd in milk. It consists of a stainless-steel cylindrical chamber about 2 ft in diameter with a bolted-on cover on one side and the other enclosed with a stainless-steel diaphragm. The diaphragm is driven electromagnetically at a frequency of 360 cps. Milk to be treated is introduced into this chamber at the outer edge of the cover and leaves the chamber at a central opening where it is subjected to the intense vibration at the center of the diaphragm. This treatment breaks up the fat globules so that no cream line can form and results in a softening and fining of the curds.

Another application of the vibration principle is an oscillator for Fourdrinier shake sections on paper machines. This device is termed a compensator. It makes use of a compensating mass in conjunction with a spring system which is built to resonate as a system with the Fourdrinier section. During operation the Fourdrinier mass and the mass of the compensator move in opposite directions so that the energies are balanced. This permits greater shake speeds and stroke with the result of better felting and higher wire speeds. This is an example of slow vibrations with a mass of several tons at something like 500 to 750 strokes per minute through an amplitude of ½ in. or so.

For experimental work with sound-wave frequency operating on liquid chemicals and living organisms, a 9-kc oscillator was found to be of optimum frequency. It depends for its operation on the magnetostricture principle. Its operation is an extension and contraction of a laminated-nickel rod activated by an alternating magnetic field. The bottom of the test cup forms the diaphragm and transfers the energy of vibration to the liquid under test within the cup. Its use in bacteriological and biological research has shown that the disintegration of bacteria is more rapid at this rate of vibration than at higher rates. Research workers in the production of stable emulsions for heavy chemical industries have also found that more energy can be introduced into the sample at this frequency than at ultrasonic frequencies.

Ultrasonic vibrations, on the order of 0.5 to 12 megacycles, have found use for the transmission of waves directed in straight lines through solids for the detection of flaws. One such electronic instrument embodies a pulse generator whose frequency is controlled by a quartz crystal. By the reflection method, one crystal may be employed as both transmitter and receiver. Ultrasonic vibrations are sent through a material under test and are reflected from the opposite end or from an intermediate point where a flaw exists. The indicator is a 9-in. cathode-ray tube on which the pattern of the wave appears, together with timing wave by which the flaw is located. The quartz-crystal searching unit must be applied to a relatively smooth and flat surface—about GE5 f* is recommended. As the search unit is moved over the reflected surface, the reflected pattern is observed and interpreted by the operator. This method of nondestructive testing is particularly valuable in the testing of large assembled equipment where disassembly is costly and inconvenient. Such cases are represented by large shafts, crank pins, and axles such as are used on large machines and locomotives.

The compressed-air high-intensity sound generator is being used to agglomerate fine particles of furnace black made from natural gas. A frequency of 3.5 kc and an intensity of 160 db is used to treat about 2,000 cu ft of gas per min and results in the recovery of about 96 per cent of the carbon black in the cyclones which follow the agglomerator tower. In general, sound-wave agglomeration can be used when the particles are below 10 to 15 microns in diameter and their concentration exceeds 2 grains per cu ft. Similar applications under consideration are soda and salt-cake recovery from paper- and pulp-mill stack gases, precipitation of sulfuric acid mist, and recovery of dust from flue gases. The generator may also have application in the dispersal of fog, in the more rapid spray drying of powdered soap, milk, and drugs, and in other fields.

Among other actual or possible applications of ultrasonics may be mentioned the acceleration of chemical reactions, modification of crystallizations, control of polymerization and depolymerization, creation and destruction of emulsions and colloidal suspensions, improvement in photographic-emulsion stability and grain size, aging of beer, wine, and whisky, degasification of liquids and foundry melts, alloying of molten metals, submarine signaling and detection of underwater objects, destruction of microorganisms, and knifeless surgery.

GRAVITATION AND CENTRIFUGAL SEPARATION

Gravity for separation has been a fundamental in mining practice for centuries. Now the same methods, certainly as to fundamentals, can be applied with advantage to many manufacturing processes. The classification of grain size by screening with perforated sheets, wire screens, and bolting cloth needs no remarks. As a review, the general principles of classification by free settling in a liquid may be stated.

---

* A surface-smoothness measure.

1. When two particles have different specific gravities, the one with the higher will fall faster.

2. Of two particles, the larger will settle faster.

3. Of two particles that will just pass through the same screen, the more nearly spherical particle will settle faster than the long slim one, and the latter will settle faster than the flat one.

4. Of two particles—one to which air bubbles adhere, the other free of bubbles—the latter will settle faster.

5. With a group of particles strongly magnetic and another group not, the former will clot together by mutual attraction and settle faster.

6. With two liquids of different density, a particle settles more rapidly in the lighter liquid.

7. With two liquids of different viscosity, a particle will settle more rapidly in the less viscous liquid.

The foregoing facts are the results of man's observations, probably extending back to the dawn of civilization. For spherical bodies, which are seldom the ones involved, Stokes's equation can be used, where the velocity of fall V under the force of gravity of a spherical particle of density ρ_p and coefficient of viscosity η is given by

$$V = (2/9\eta)gr^2(\rho_p - \rho_d)$$

Tables of settling times for different substances under the influence of gravity may be found in texts on ore dressing and thus save much calculation. Fine abrasives are commonly classified by settling in water or light oil. When ground in water and followed by fractional sedimentation, the process is called levigation. The product is often referred to as 2-hr water, 4-hr water, etc., as a statement of fineness. Concentrators, coarse-sand jigs, fine-sand jigs, flotation processes, etc., as described in mining literature, can be reviewed with profit if quantities of materials are to be classified according to size.

The centrifuge and centrifugal separator permit the use of a force many times that of gravity, and the larger centrifugal field makes possible the separation of particles of smaller size and mass difference. If we consider the force in a centrifuge as a ratio to the force due to gravity and express it as pounds force on the periphery of the basket,

$$Fg = \tfrac{1}{2}\omega^2 D \qquad \text{or} \qquad F = Dn^2/5{,}870$$

where F = force, lb, at the periphery of the basket
g = 32.2
n = rpm
ω = radians per sec
D = diameter of the basket, ft

Centrifugal extraction is usually the problem of removing a liquid from a solid mass. The problem of the extractor design is one of balancing the load or else providing structure and bearing that will endure the unbalance. Special-purpose machines are made for the extraction in chemical industries, sugar refineries, coal washing, laundries, chips in machine shops, and many other kinds of waste. Extractors for different materials will require different designs, and the problem of loading and unloading the machine is often the most difficult factor encountered.

Separators for milk, oil, and other liquids call for a bowl- or plate-rotating member rather than a basket. The problem of balance is largely eliminated, but centrifugal force becomes such that particular attention must be given to the strength of rotating parts. In cream and oil separators, groups of hollow cones surround the central shaft, and the liquid is fed to the cones continuously, the heavy portion being carried in a continuous flow to the low outside edges of the cones, while the cream rises to the top of the cones in the center. Other arrangements embody the same principles.

Considerable work has been done in recent years on ultracentrifuges. Professor Svedberg's early ultracentrifuges gave centrifugal fields of 500 to 15,000 gravity. His second type of oil-turbine ultracentrifuge will give centrifugal forces within the range of 15,000 to 750,000 gravity. *This is an example of results that can be achieved by precise design.

RADIOACTIVITY

Natural radioactivity was discovered by Becquerel in 1896. The same year the Curies isolated from barium, radium, which has 3 million times the activity of barium. They isolated a substantial amount (about 0.1 gm of radium chloride) by 1902. It was later found that this element was a step in the spontaneous transmutation of radioactive uranium into a stable isotope of lead. In 1919, Lord Rutherford accomplished the artificial transmutation of nitrogen into carbon. This was the first answer to the alchemists' search of centuries for conversion of one element into another until they finally lost hope, and chemists incautiously declared that the elements were immutable. After 1930 the advance in this field was very rapid, and in 1939 nuclear fission was discovered.

In the structure of matter there are seven known building blocks*—the proton, the neutron, the positive meson, the negative meson, the positron, the electron, and the neutrino—whose existence is suspected but not demonstrated. Three of these particles are fundamental—the proton, neutron, and electron. The atomic weight of the element is determined by the number of protons and neutrons combined to form the nucleus. The atomic number and chemical properties of the element are determined by the number of protons in the nucleus. If a proton is added or subtracted from the nucleus, the chemical characteristics of the element are completely changed; and since each positron carries a positive charge, its electric charge is increased or decreased by one unit. If a neutron is added or removed, only the weight of the atom is changed. The weight of a neutron is approximately equal to the weight of a positron. For each positron in the stable atom there is an electron which must carry a negative charge equal in magnitude to the positive charge in the positron. Hence the number of electrons in a stable atom is equal to the atomic number of the element. The electron has a mass about 1/1,840 the mass of the proton or neutron. The atomic weight of an atom is found by comparing its weight with the weight of the oxygen atom, O = 16.0000. The number of neutrons in an atom is the atomic weight minus the atomic number; *e.g.*, $_{92}U^{238}$ has 238 − 92 = 146 neutrons as well as its 92 positrons and 92 electrons.

Isotopes are substances having identical chemical properties but different atomic weights. For example, zinc is a mixture of substances having atomic weights of 64, 66, 67, 68, and 70 in such proportions as to give a mean value of 65.38 for the atomic weight of zinc. These are stable isotopes having the nuclear charge equal to the number of extranuclear electrons. Zinc may also have the radioactive, or unstable isotopes, 63, 65, and 69. Carbon, $_6C^{13}$, is a natural heavy isotope which exists as about 1.1 per cent with $_6C^{12}$ as the other 98.9 per cent of normal carbon. Four other isotopes of carbon can be produced. Natural unstable radioactive isotopes change to stable ones by emitting particles which in the early days of their discovery, when little was known of their character, were termed alpha, α, beta, β, and gamma, γ, rays. Further research revealed that α particles consist of two protons and two neutrons with two units of positive charge, really nucleuses of helium atoms. Beta particles are electrons and hence have unit negative charge. Gamma rays are similar to very-high-voltage X-rays, contain no charge, and cannot be deflected by a magnetic field. They have penetrating power exceeding ordinary X-rays, and it was soon discovered that they have an inhibitory action on many cancerous growths without destroying adjacent healthy tissue when the treatment is suitable. When a radioactive substance decomposes, the emission of an α-particle transmutes the element into a new substance with an atomic number of two units less and an atomic mass of four units less. When it emits a β-particle, it changes to a substance with an atomic number one unit greater but with no change in atomic mass. The time that it takes for a radioactive element to decay to half its original activity is called its half-life. The half-life of any radioactive isotope is a definite value, but different isotopes of the same element have greatly varying half-lives; for example, the half-life of $_6C^{10}$ is 8.8 sec, that of $_6C^{11}$ is 20.5 min, and that of $_6C^{14}$ is 5,000 years.

The uranium pile is a massive structure of alternate layers of pure uranium and carbon. The first one made had over 6 tons of uranium in it. Cavities are maintained in the pile for the introduction of cadmium rods, which will arrest the reaction by absorbing neutrons and will keep the reactor from getting out of hand. Pure carbon rods, called moderators, may also be inserted to slow down the neutrons without absorbing them. In this manner the pile produces quantities of slow-speed neutrons which are effective in disintegrating nucleuses. The sample to be bombarded is placed in welded aluminum vessels and inserted into openings in the pile where the neutrons penetrate the aluminum without being absorbed and transform the enclosed element into a radioactive isotope. This transformation is accomplished in several ways. If the nucleus of the atom picks up a neutron, it may emit an α-particle, a positron, or a γ-ray. Radioactive carbon C^{14} is readily made in the uranium pile by the action of slow neutrons on nitrogen.

---

* 1950.

$$N^{14} + n^1 \rightarrow C^{14} + H^1$$

A solution of ammonium nitrate may be subjected to the neutron bombardment, and the result is a bicarbonate ion. Radioactive-carbon samples contain as much as 5 per cent of the radioactive isotope.

The curie is the unit of measure of radioactivity. One curie of radium is approximately equal to 1 gram of the element. It is actually an amount of the substance such that 3.71×10^{10} atoms per sec of the substance are undergoing disintegration. The unit is a large one, and it is found convenient to state radioactivities of commercial isotopes in millicuries.

The Geiger-Mueller counter is commonly used to determine the radioactivity of a sample of an isotope. This may be a metal cylinder for one electrode and a concentric axial wire for the other, all enclosed in a glass vessel with the enclosed gas at a pressure of a few centimeters of mercury. A direct voltage a little below the glow-discharge voltage is applied to the electrodes. When any ionizing particle enters the ionizing chamber, it produces ions which produce other ions by collision. A momentary current flows through an amplifier, similar to an amplifier on a radio receiver, and an automatic counter records the number of pulses.

Radioactive isotopes have innumerable applications, and while their use has been extensive in medicine, the extension of the use to industrial processes is taking place rapidly. For example, the sodium of ordinary table salt is activated and made into an isotonic saline solution and introduced into the veins of a patient. A Geiger counter will show the efficiency, time, and extent of the circulation. The importance of this will be recognized if it is considered that a limb with defective circulation is to be amputated. The point where effective circulation ends is readily found. Many organs of the body selectively absorb certain elements or compounds; *e.g.*, the thyroid gland uses iodine in synthesizing thyroxine, and the bones selectively absorb phosphorus. These facts point to the use of elements or compounds containing radioactive material that will go directly to the desired part of the body and there release their radioactivity. This can be used as a tracer or may even be used for radiation treatment where X-rays cannot be used. The time of dosage is also controllable by selecting an isotope whose life is of the desired magnitude, it being remembered that their half lives may be a few seconds or thousands of years. As tracer elements the radioactive isotopes are revealing many facts otherwise unobtainable. Many biochemical reactions can be studied and their rates determined by following the course of the tracer atoms.

This tagging of atoms aids, too, in the study of plant physiology and plant pathology. Phosphorus (P^{32}), because of the extensive use of phosphorus in plant growth, is suitable for these studies as well as for tracing the path of fertilizer from its place in the soil through the plant tissues to the fruit. C^{14} may be used in studies of photosynthesis by exposing the leaves that have grown in an atmosphere of radioactive carbon dioxide to photographic film. The imprint of every part of leaf or stem that contains the radioactive element will be shown on the film.

In **metallurgical processes** the importance of radioactive tracers will be obvious. If it is suspected that a particular element is being carried away in the slag, a quick reading with a Geiger counter before the metal is poured will indicate the presence or absence of the required amount. A textile or paper operation may be hampered by accumulations of static electricity. Small quantities of radioactive isotopes suitable for alloying with parts of the machine such as rolls or shafts would act to discharge the static electricity from an electrified body.

Safety of personnel in radioactive work can be assured by careful supervision. When tolerances in counts per minute on Geiger counters for various articles of laboratory clothing, for workers' hands, and for other parts of the body are established, it is a simple matter to perform checks at proper daily periods. A dental X-ray film with a paper clip on it can be worn by the worker and replaced weekly. The removed film is then developed and observed for an image of the paper clip on its emulsion and density of background measured. A regular commercial film-badge service is also available for health-maintenance purposes. Normal tolerance is conventionally taken as 0.1 roentgen per 24-hr period. The badges are usually equipped with two films, one of high sensitivity, the other of low sensitivity. A weekly exchange of badges between the supplier and the subscriber ensures a constant check on the radioactivity to which the worker is exposed. A record of the measured roentgens is kept and reported to the subscriber.

Nuclear fission of uranium occurs when a neutron collides with a U^{235} nucleus and combines with it, forming a U^{236} nucleus. Since the resulting nucleus is unstable, it will split into two fragments, each itself an atomic nucleus the sum of whose atomic weights is 92. Suppose an atom split into strontium and xenon nucleuses with the production of 17 neutrons:

$$_{92}U^{235} + {}_0n^1 \rightarrow {}_{38}Sr^{88} + {}_{54}Xe^{131} + 17\,{}_0n^1$$

There must be a conservation of charge $38 + 54 = 92$ and mass number

$$88 + 131 + 17 = 236$$

Usually there is unsymmetrical splitting with one nucleus having a mass number between 80 and 110, and the other between 125 and 155 being formed. This nuclear fission results in the emission of a large amount of energy, about 5×10^{12} cal per gram-atom (235 grams of U). This is about 38.2×10^9 Btu per lb. It is about 2,800,000 times the amount of energy produced by burning the same amount of coal, or 14,600,000 times the amount liberated by 1 lb of nitroglycerine. Uranium as a source of energy may be 2,800,000 times as valuable as coal. Thorium isotope $_{90}Th^{232}$ has also been shown to undergo fission under the bombardment of fast neutrons. It may be that all the elements with atomic number greater than 90 can be made to react to release atomic energy. There are large amounts of thorium and uranium in the earth's crust—about 12 parts per million and 4 parts per million, respectively. Thorium is the thirty-fifth element in abundance and uranium the forty-sixth; the two together about equal in amount lead, which is thirty-first in abundance.

It cannot be assumed from the foregoing discussion that commercially produced atomic power is just around the corner. Methods of handling such prodigious quantities of power and temperature must be found. Ways may be found to release the energy efficiently and slowly, and long-time prospects look bright. There are several essentials in the problem of making atomic power a commercial reality. The energy must be produced in a usable form; the material used must have a usable rate of generating power; there must be adequate stocks of the fuel to operate a power industry; wastage of this costly material must be prevented, and the valuable ashes—unspent nuclear fuel—must be recovered. Improvement in fuel-burning plants may be safely continued without fear of early obsolescence because of atomic power. There will be ample warning before atomic power even supplements the present prime forms of energy release.

  - *D*. Solution of higher order equations
- XII. Empirical equations
  - *A*. Parabolic and hyperbolic curves, $y = ax^b$ (parabolic when $b > 0$ and hyperbolic when $b < 0$)
  - *B*. Exponential curves, $y = ae^{bx}$
  - *C*. Parabolic or hyperbolic curves, $y = a + bx^n$ (where n is known)
  - *D*. Hyperbolic curves, $y = x/(a + bx)$, $x/y = a + bx$, or $1/y = (a/x) + b$
  - *E*. Parabolic or hyperbolic curves, $y = ax^b + c$
  - *F*. Exponential curves, $y = ae^{bx} + c$
  - *G*. Parabola, $y = a + bx + cx^2$
  - *H*. Hyperbolic curves, $y = x/(a + bx) + c$
  - *I*. Logarithmic or exponential curves, $\log y = a + bx + cx^2$, or $y = ae^{bx+cx^2}$

GRAPHICAL MATHEMATICS

BY R. D. DOUGLASS, PH.D., SC.D.

Professor of Mathematics, Massachusetts Institute of Technology

GEOMETRICAL CONSTRUCTIONS

To Bisect a Line AB (Fig. 29-1). From A and B as centers, and with equal radii, describe arcs intersecting in C and D, and draw CD, which bisects AB at E.

To Construct a Perpendicular to a Given Line from a Point A **Outside the Line** (Fig. 29-2). With A as a center, describe an arc cutting the line in B and C, and bisect BC at D. D is the foot of the perpendicular.

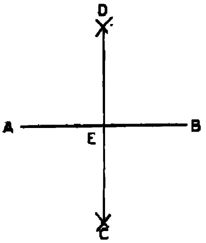

FIG. 29-1. To bisect a line AB.

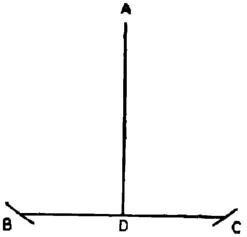

FIG. 29-2. To construct a perpendicular to a given line from a point A outside the line.

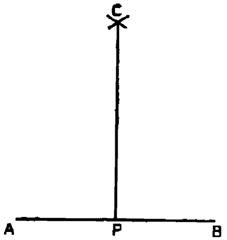

FIG. 29-3. To construct a perpendicular to a given line at a given point P.

To Construct a Perpendicular to a Given Line at a Given Point P. Lay off $PA = PB$ (Fig. 29-3), and with A and B as centers draw arcs intersecting at C. PC is the required perpendicular.

To Divide a Line into n **Equal Parts** (Fig. 29-4). Through A draw a line AC making any angle with AB, and lay off n equal segments on the line. Connect the end of the last segment with B, and draw parallels through the other divisions. These parallels will divide the line AB into n equal parts.

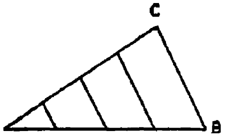

FIG. 29-4. To divide a line into n equal parts.

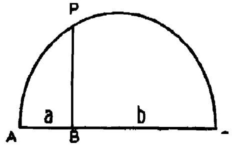

FIG. 29-5. To construct a mean proportional to two lengths a and b.

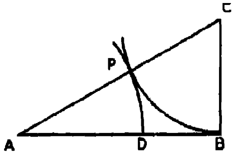

FIG. 29-6. To divide a line AB in extreme and mean ratio.

To Construct a Mean Proportional to Two Lengths a **and** b (Fig. 29-5). Lay off $AB = a$, $BC = b$, and construct a semicircle on AC as a diameter. Draw a perpendicular at B meeting the circle at P. $BP = \sqrt{ab}$.

To Divide a Line AB **in Extreme and Mean Ratio** (Fig. 29-6). At B construct a perpendicular BC equal to one-half AB, and connect the points A and C. Along CA lay off $CP = CB$, and along AB lay off $AD = AP$. D is then the required point, *i.e.*, $(AD)^2 = AB \cdot BD$.

To Bisect an Angle AOB **(Fig. 29-7).** Lay off $OA = OB$. With A and B as centers, describe arcs intersecting at C. OC is the required bisector.

To Pass a Circle through Three Given Points A, B, **and** C **or to Locate the Center of a Given Circle (Fig. 29-8).** Draw the perpendicular bisectors of AB and BC. These will intersect at the center O.

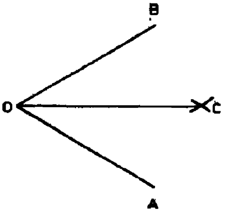

Fig. 29-7. To bisect an angle.

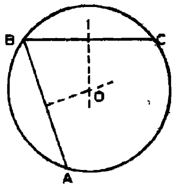

Fig. 29-8. To pass a circle through three given points A, B, and C or to locate the center of a given circle.

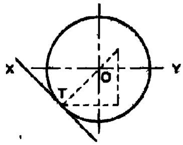

Fig. 29-9. To construct a tangent to a circle at a given point of contact T.

To Construct a Tangent to a Circle. (1) At a given point of contact T (Fig. 29-9): Draw TX perpendicular to OT. (2) From a given external point A (Fig. 29-10): Construct a semicircle on OA intersecting circle at T; then T is the required point of tangency.

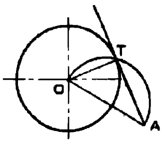

Fig. 29-10. To construct a tangent to a circle from a given external point A.

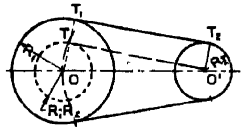

Fig. 29-11. To construct a common tangent to two given circles.

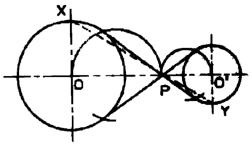

Fig. 29-12. To construct a common tangent to two given circles.

To Construct a Common Tangent to Two Given Circles. (1) Let O and O' be the centers and R_1 and R_2 the radii ($R_1 > R_2$) (Fig. 29-11). With O as center draw a circle of radius $R_1 - R_2$; draw a tangent to this circle from O'; through point of tangency T draw OT_1; draw $O'T_2$ parallel to OT_1. T_1 and T_2 are the points of tangency. (2) Draw line XY (Fig. 29-12) intersecting OO' at P; construct tangents to the given circles from P.

To Pass a Circle through Two Fixed Points A **and** B **and Tangent to a Given Line** L **(Fig. 29-13).** Let AB cut the line L in C. Pass any circle through A and B, and let CT be tangent to this circle. Along L lay off CD and CE equal to CT. Then both D and E satisfy the condition of tangency. The centers of the required circles lie on the perpendicular bisector of AB.

To Draw a Circle Tangent to Each of Three Given Lines, No Two of Which Are Parallel (Fig. 29-14). Draw the bisectors of the three angles; these will meet in the center O. The perpendiculars from O to the three lines will determine the points of tangency.

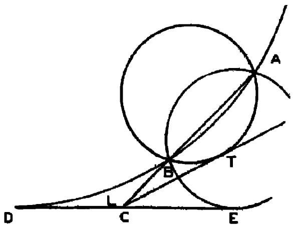

Fig. 29-13. To pass a circle through two fixed points A and B and tangent to a given line L.

To Construct a Circle of Radius R **Tangent to Each of Two Fixed Lines** XY **and** MN **(Figs. 29-15a, 29-15b).** Draw lines parallel to and at a distance R from each of the lines. The intersection of these lines is the center of the circle.

To Construct a Circle of Radius R **Tangent to a Circle of Radius** R_1 **with Center at** O **and Tangent to a Fixed Straight Line** MN **(Fig. 29-16).** Draw a line XY parallel to MN and at a distance R from it. With O as a center and $R + R_1$ as a radius, describe an arc intersecting line XY at A. A is the center of the desired circle.

To Construct a Circle of Radius R Tangent to Each of Two Fixed Circles of Radii R_1 and R_2 (Fig. 29-17). Draw an arc of radius $R_1 + R$ with the center of the circle of radius R_1 as a center. Draw an arc of radius $R_2 + R$ with the center of the circle of radius R_2 as a center. These arcs intersect at X, the center of the desired circle.

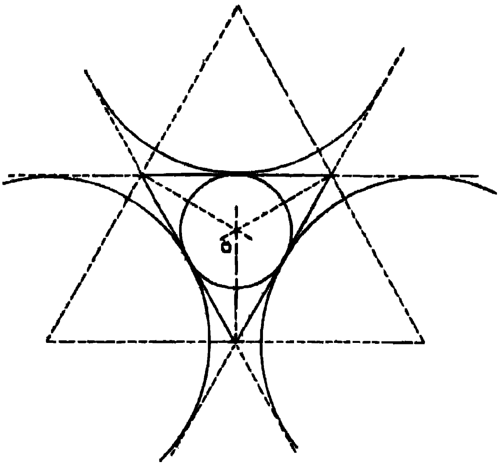

FIG. 29-14. To draw a circle tangent to each of three given lines, no two of which are parallel.

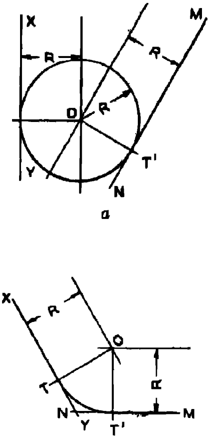

FIG. 29-15. To construct a circle of radius R tangent to each of two fixed lines.

To Construct a Circle of Radius R Tangent to Two Inside Circles of Radii R_1 and R_2, Respectively (Fig. 29-18). Draw an arc of radius $R - R_1$ with the center of the circle of radius R_1 as a center. Draw an arc of radius $R - R_2$ with the center of the circle of radius R_2 as a center. These arcs intersect at X, the center of the desired circle.

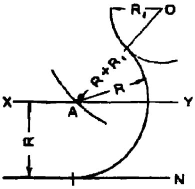

FIG. 29-16. To construct a circle of radius R tangent to a circle of radius R_1 with center at O and tangent to a fixed straight line.

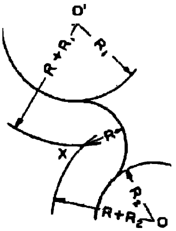

FIG. 29-17. To construct a circle of radius R tangent to each of two fixed circles of radii R_1 and R_2.

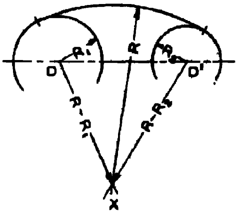

FIG. 29-18. To construct a circle of radius R tangent to two inside circles of radii R_1 and R_2.

Parabola. *Equation.* $x^2 = a^2y/b$ (Fig. 29-19).

Construction. Divide the distance a into n equal parts and the distance b into the same number of equal parts. Draw lines from O to the points of division of b and lines to each of the divisions of a parallel to the y-axis. The intersections of the lines bearing the same numbers in Fig. 29-20 will be points on the required parabola.

The distance from the vertex of the parabola $x^2 = (a^2/b)y$ to its focus and to its directrix is $a^2/4b$.

To Construct a Tangent to the Parabola at a Point P on the Parabola (Fig. 29-21). Lay off $OB = OA$ or $FP = FB$. BP is the required tangent.

To Construct a Tangent to the Parabola from Any External Point P (Fig. 29-22). With P as a center and radius PF, draw a circle cutting the directrix at A. Draw AB parallel to OF; then B is the required point of contact.

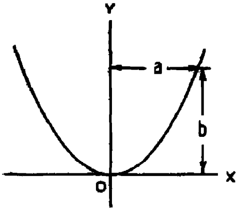

FIG. 29-19. Parabola $x^2 = a^2y/b$.

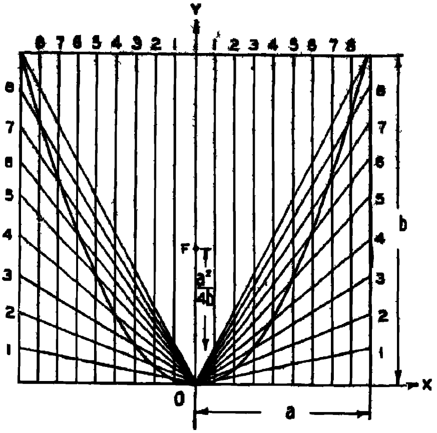

FIG. 29-20. To construct the parabola $x^2 = a^2y/b$.

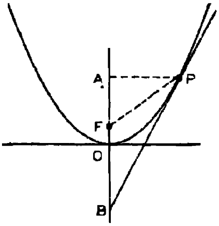

FIG. 29-21. To construct a tangent to the parabola at a point P on the parabola.

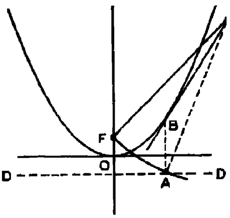

FIG. 29-22. To construct a tangent to the parabola from any external point P.

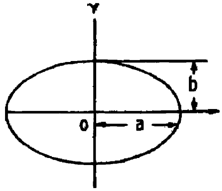

FIG. 29-23. Ellipse.

Ellipse. *Equation:* $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$ (Fig. 29-23).

Construction: To construct an ellipse of length $2a$ and width $2b$ $(a > b)$, divide a into n equal intervals, and divide b into n equal intervals. Draw lines from the lower end of the minor axis (Fig. 29-24) through the end of each interval into which a is divided, and draw lines from the upper end of the minor axis through the end of each interval into which b is divided, labeling each line as indicated in Fig. 29-24. The intersections of like numbered lines lie on an ellipse.

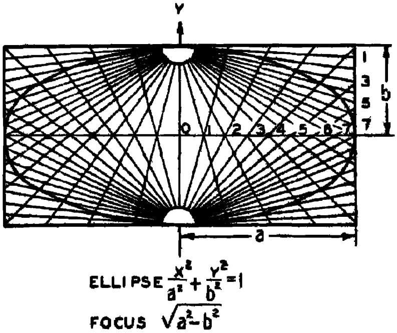

FIG. 29-24. To construct the ellipse.

The distance from the center of the ellipse $(x^2/a^2) + (y^2/b^2) = 1$ to a focus is $\sqrt{a^2 - b^2}$.

To Construct a Tangent to an Ellipse. (1) At a point on the ellipse: Bisect the angle between PF_1 and PF_2 (Fig. 29-25). (2) From a point P external to the ellipse (Fig. 29-26): With P as a center and radius PF_2, draw an arc; with F_1 as a center and radius $2a$, draw an arc intersecting the first in X and Y. XF_1 intersects the ellipse at T_1, YF_1 intersects at T_2. T_1 and T_2 are the points of tangency.

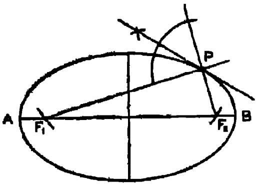

FIG. 29-25. To construct a tangent to the ellipse at a point on the ellipse.

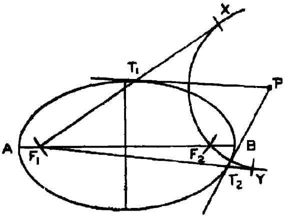

FIG. 29-26. To construct a tangent to the ellipse from a point P external to the ellipse.

FIG. 29-28. To construct the hyperbola.

Hyperbola. *Equation:* $\frac{y^2}{a^2} - \frac{x^2}{k^2} = 1$ (Fig. 29-27).

Construction. To construct a section of a hyperbola of width $2b$ and height c with its vertex at a distance a from the center of the hyperbola, divide b and c into n equal intervals (Fig. 29-28). Draw lines from the lower vertex through the end of each interval into which b is divided, and draw lines from the upper vertex through the end of each interval into which c is divided, labeling the lines as indicated in Fig. 29-28. The intersections of like numbered lines lie on a hyperbola. The opposite branch of the hyperbola is constructed in a similar manner.

The distance from the center of the hyperbola $(y^2/a^2) - (x^2/k^2) = 1$ to a focus is $\sqrt{a^2 + k^2}$.

To Construct a Tangent at the Point P on the Hyperbola (Fig. 29-29). Draw PA and PB parallel to the asymptotes, and let OC equal $2OA$ and OD equal $2OB$. CD is the required tangent at P.

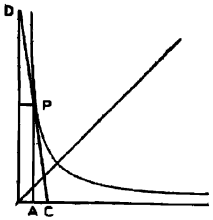

Fig. 29-29. To construct a tangent to the hyperbola.

GRAPHICAL REPRESENTATION OF FUNCTIONS

Scale. A graphical scale is a curve or straight line on which are marked a series of points or strokes corresponding to a set of numbers arranged in order of magnitude. If the distances between successive strokes are equal, the scale is said to be *uniform* (Figs. 29-30*a*, 29-30*b*). If the distances between strokes are unequal, the scale is said to be nonuniform (Fig. 29-30*c*).

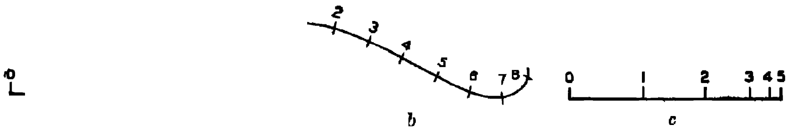

Fig. 29-30. Scales: (*a* and *b*) uniform; (*c*) nonuniform.

Representation of a Function by a Scale. Consider the function u. Lay off from a fixed point O on a straight line or curve lengths equal to mu units; mark at the strokes indicating the end of each segment the corresponding value of u. If m is unity and the unit of measure is an inch, the resulting scale is $x = u$ inches (Fig. 29-31*a*).

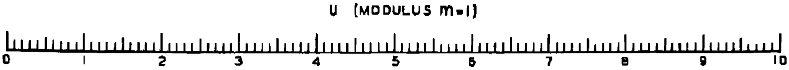

Fig. 29-31*a*.

For a function u^2 of the variable u; from the table

$$u = 0, 1, 2, 3, \cdot \quad \cdot 10$$
$$u^2 = 0, 1, 4, 9, \cdot \quad \cdot 100$$

and lay off the distances $x = mu^2$. If $m = \frac{1}{10}$ and the unit of measure is the inch, then u will be the number on the scale at the end of $\frac{1}{10}u^2$ inches measured from the fixed point, or origin, of the scale (Fig. 29-31*b*).

Fig 29-31*b*.

m is called the scale *modulus*, and $x = mf(u)$ is called the *equation of the scale* of the function $f(u)$. For a given range of the variable u and for a desired length of scale, m is determined. Thus if it is desired to represent $f(u)$ on a scale l inches long and u varies from $u = u_0$ to $u = u_l$, then the equation of the scale is $x = mf(u)$. When $u = u_0$, $x_0 = mf(u_0)$; and when $u = u_l$, $x_l = mf(u_l)$; and it follows that

$m[f(u_l) - f(u_0)] = x_l - x_0 = l$. Therefore

$$m = \frac{l}{f(u_l) - f(u_0)}$$

and the resulting scale equation is

$$x = \frac{l}{f(u_l) - f(u_0)} f(u)$$

Two of the most commonly used scales are $x = mu$ (uniform) and $x = m \log u$ (nonuniform). These and other scales are illustrated in Figs. 29-31*a* to 29-31*i*.

Figure 29-31*c* shows a uniform scale of length 10 in. with a range of values from 0 to 1. Its modulus m is 10, and its equation is $x = 10u$. Figure 29-31*a* shows the same scale reduced in size to one-tenth that of Fig. 29-31*c*, and its equation is $x = u$.

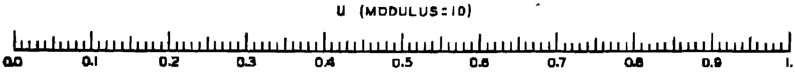

Fig. 29-31*c*.

Figure 29-31*d* shows a scale of log u and is called a logarithmic scale. The range of values of u is from 1 to 10, its original length is 10 in., and its scale equation is $x = 10 \log u$. This is the *C* scale of the so-called 10-in. slide rule. The equations of the *A* and *K* scales on the same slide rule are $x = 5 \log u$ and $x = {}^{10}\!/\!_3 \log u$, respectively.

Fig. 29-31*d*.

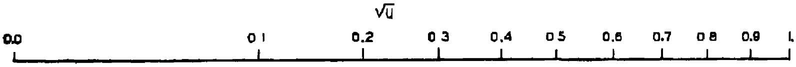

Fig. 29-31*e*

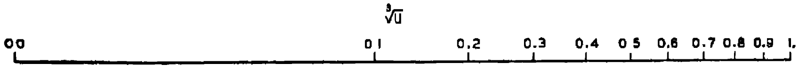

Fig. 29-31*f*.

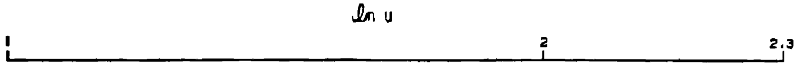

Fig. 29-31*g*.

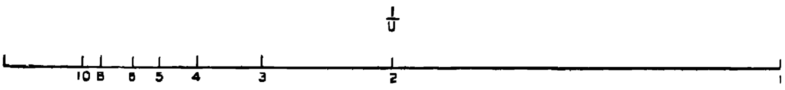

Fig. 29-31*h*.

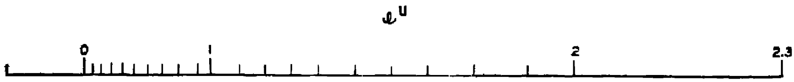

Fig. 29-31*i*.

When a scale of $mf(u)$ is constructed, any scale $kmf(u)$ may be immediately obtained by use of similar triangles. Figure 29-32 shows how a scale of log u with any modulus may be obtained. Figures 29-33, 29-34 show the scales of sin u and log (10 sin u).

Stationary Scales. A relation between two variables u and v of the form $v = f(u)$ can be represented by constructing the two scales $x = mf(u)$ and $x = mv$ on the opposite sides of the same axis. Each scale has the same modulus and is measured from a common fixed point or origin. In some cases it may be convenient to represent the functional relationship $\varphi(v) = f(u)$ directly without transforming the equation to $v = \varphi^{-1}[f(u)]$. It is evident that the adjacent scales are $x = mf(u)$ and $x = m\phi(v)$.

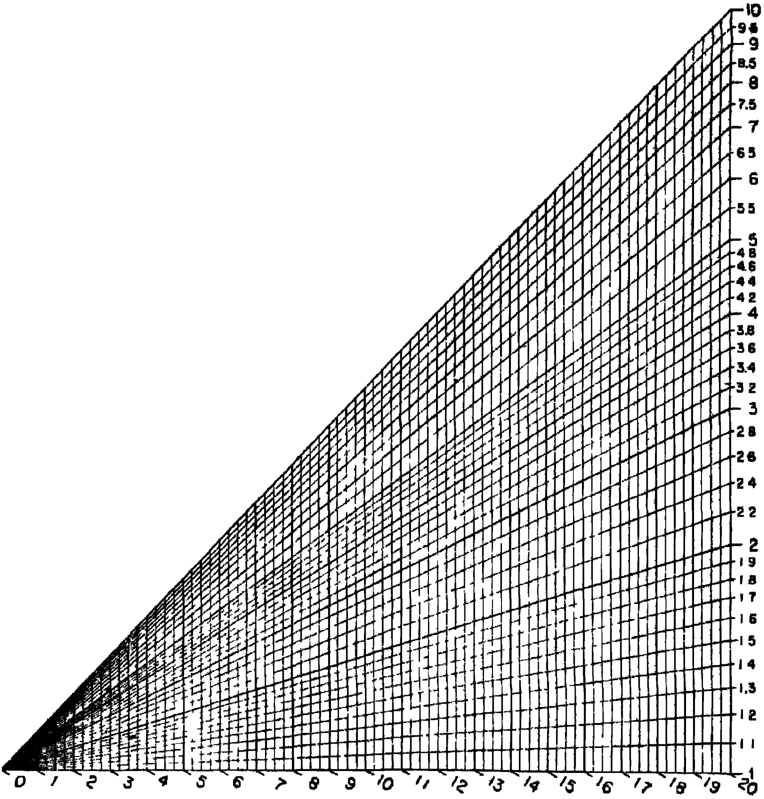

FIG. 29-32. Scale for log u (any modulus).

The scales previously mentioned are called *natural scales*. Usually it is desirable o use logarithmic scales in representing relationships of the form $\phi(v) = f(u)$ or $= f(u)$. The following illustrations show the use of the above scales for the rela- onship $u = \sqrt{v}$.

$$u = \sqrt{v} \qquad \text{and} \qquad mu = m\sqrt{v} \tag{1}$$

Using the scales in Figs. 29-31c, 29-31e, we have the stationary scales shown in ig. 29-35.

$$u^2 = v \qquad \text{and} \qquad mu^2 = mv \tag{2}$$

Using the scales in Figs. 29-31a, 29-31b we have the stationary scales shown in ig 29-36.

$$u = \sqrt{v} \qquad 2 \log u = \log v \qquad \text{and} \qquad m(2 \log u) = m \log v \tag{3}$$

Using the scales of Figs 29-31d or 29-32, we have the stationary scales shown in Fig. 29-37. It is to be noticed that, whenever logarithmic scales are used, neither

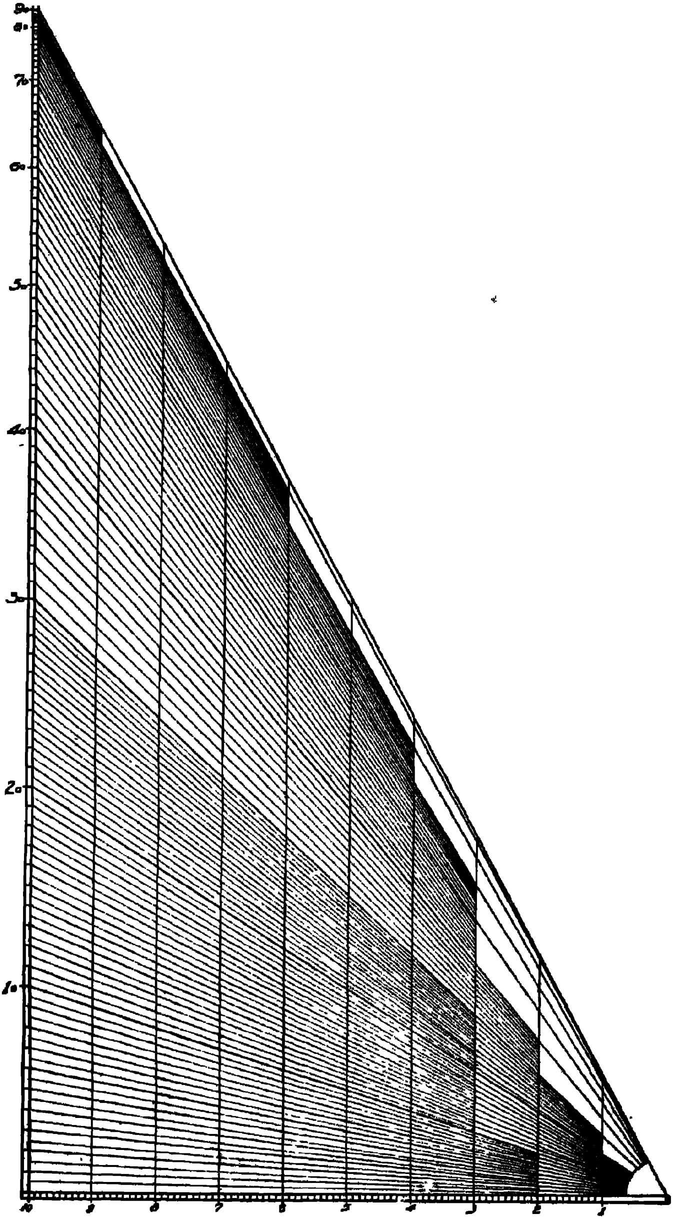

FIG. 29-33. Scale for sin u (any modulus).

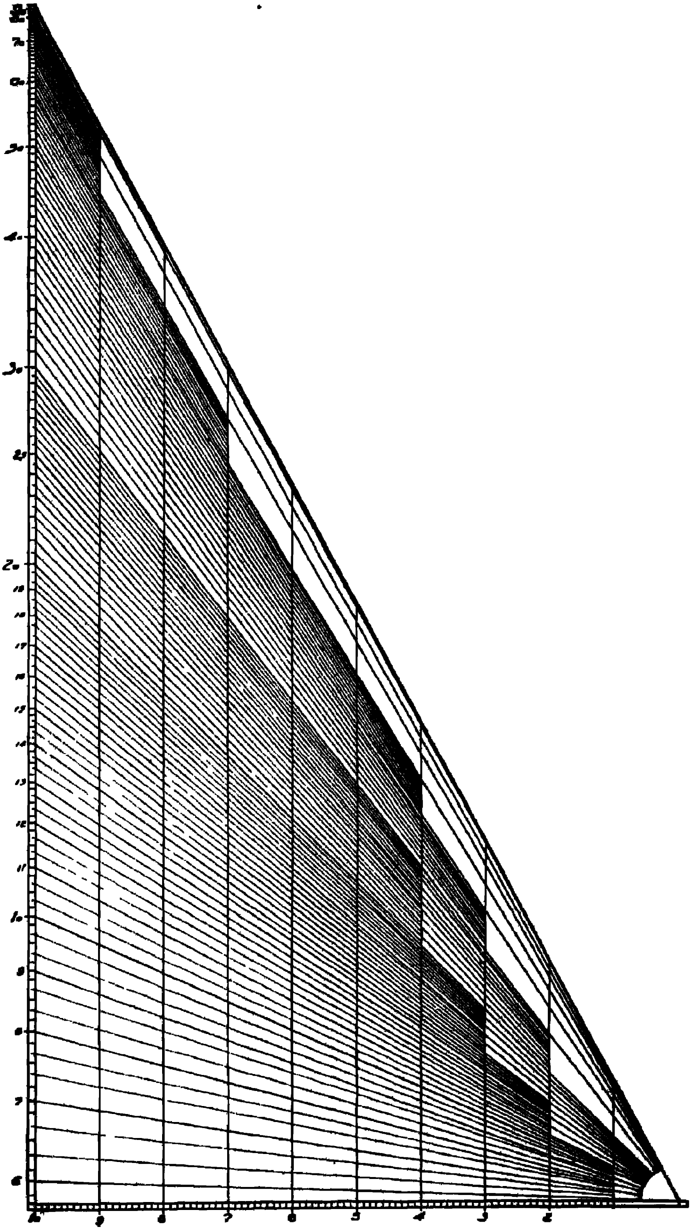

Fig. 29-34. Scale for log (10 sin u) [any modulus].

u nor v can be taken to be zero. However, because of the cyclic character of the logarithmic scale, any number on either scale may be taken as that number multiplied by any positive or negative integral power of 10.

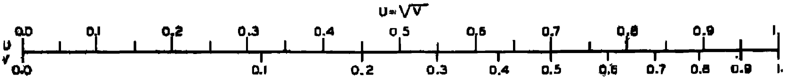

Fig. 29-35.

Fig. 29-36.

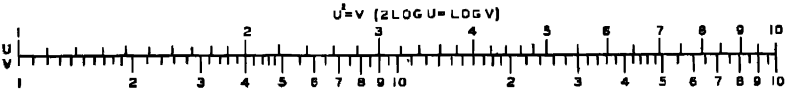

Fig. 29-37.

Adjacent stationary scales may be used to advantage in representing the relationship between the two variables in a conversion formula. Consider the formula

$$I = 0.3937C$$

which converts centimeters to inches and vice versa. Assume that C has values from 0 to 25 and that the length of the scale is to be 10 in. approximately.

Using logarithms,

$$\log I = \log C + \log 0.3937$$

Since the constant term log 0.3937 affects only the position of the scales with respect to each other, it can be neglected in the process of calculating the scale modulus m.

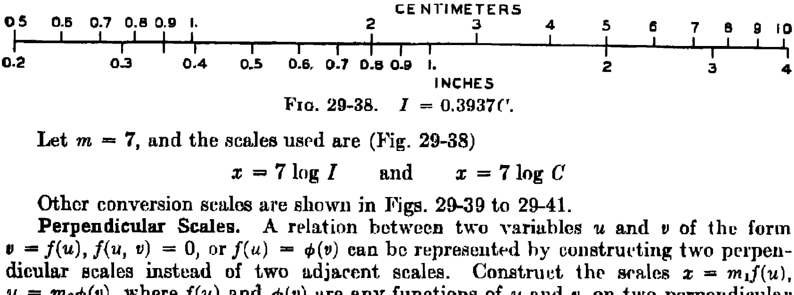

Fig. 29-38. $I = 0.3937C$.

Let $m = 7$, and the scales used are (Fig. 29-38)

$$x = 7 \log I \qquad \text{and} \qquad x = 7 \log C$$

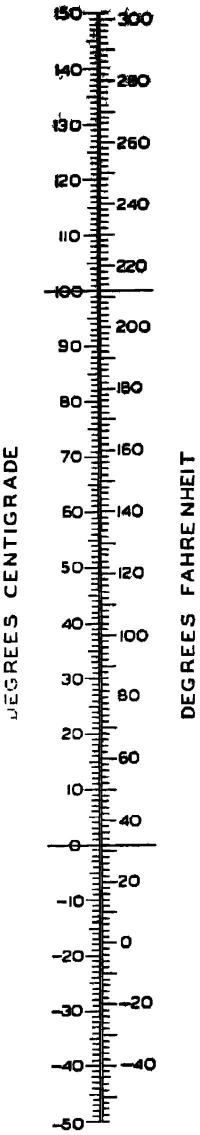
Other conversion scales are shown in Figs. 29-39 to 29-41.

Perpendicular Scales. A relation between two variables u and v of the form $v = f(u)$, $f(u, v) = 0$, or $f(u) = \phi(v)$ can be represented by constructing two perpendicular scales instead of two adjacent scales. Construct the scales $x = m_1 f(u)$, $y = m_2\phi(v)$, where $f(u)$ and $\phi(v)$ are any functions of u and v, on two perpendicular axes, and through the points marked on these scales draw perpendiculars to the axes. Any pair of values of u and v that satisfies the equation $f(u, v) = 0$ will determine a point in the plane of the axes. The locus of all such points is a curve which is said to represent the functional relationship $f(u, v) = 0$. The rectangular or cartesian equation of the curve, referred to the x- and y-axes, is found by solving for u and v from the scale equations and substituting these values in the equation $f(u, v) = 0$.

It is evident that the nature of the locus will vary with the equations of the scales. For many purposes scale equations will be chosen so that the resulting locus will be a straight line.

Various Types of Coordinate Paper. *Rectangular.* The equations of the scales are $x = m_1u$ and $y = m_2v$. With the exception of a linear relationship between u and v, the locus of $f(u, v)$ will be a curve.

The graph of the curve $uv = 12$ is shown in Fig. 29-42.



$C = \frac{5}{9}(F - 32)$

Fig. 29-39.

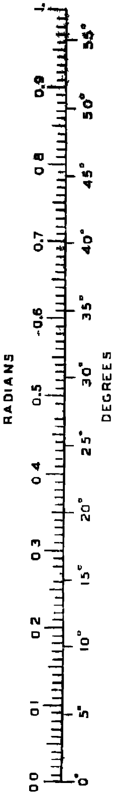


Fig 29-40 Relationship of degrees and radians.

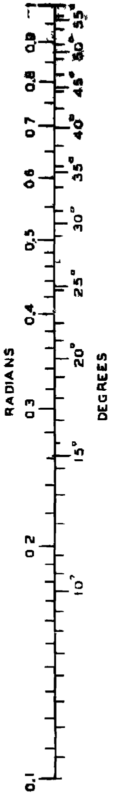

Fig 29-41 Relationship of degrees and radians.

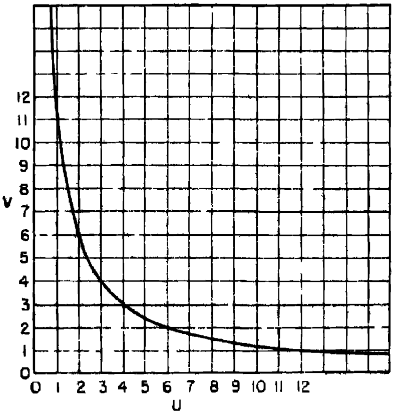

Fig. 29-42. $uv = 12$.

Logarithmic. If the scales $x = m_1 \log u$ and $y = m_2 \log v$ are marked off on the x- and y-axes, respectively and perpendiculars are drawn to both axes, there will result a logarithmic coordinate paper. The prepared logarithmic paper usually has scales of the same modulus. For example, if we are to plot the graph of $u^pv^q = k$, where p, q, and k, are constants, on logarithmic paper, the result will be a straight line. If $u^pv^q = k$, then $p \log u + q \log v = \log k$. Now if the perpendicular scales are $x = m \log u$ and $y = m \log v$, then $(p/m)x + (q/m)y = \log k$, which is a straight line.

EXAMPLE: Sketch the graph of the curve $uv = 12$ on logarithmic coordinate paper Since $\log u + \log v = \log 12$, the equations of the scales are $m \log u$ and $m \log v$ (Fig. 29-43).

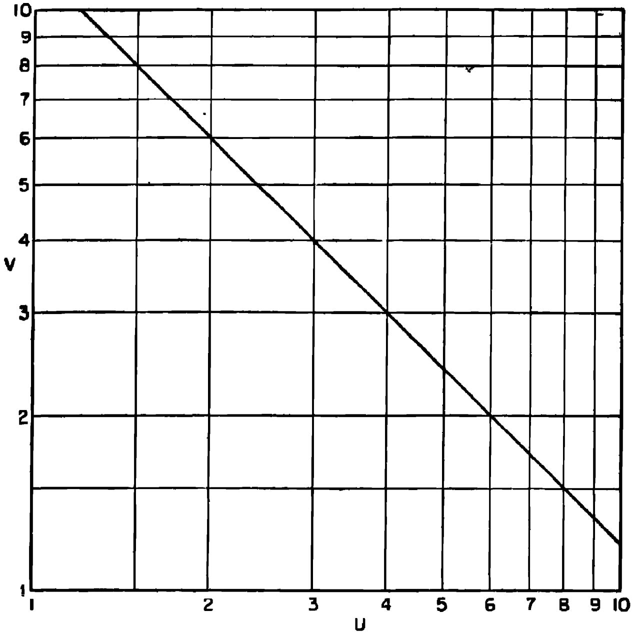

FIG. 29-43. $uv = 12$ ($\log u + \log v = \log 12$).

Semilogarithmic. If $u = ab^v$, where a and b are constants, then

$$\log u = v \log b + \log a$$

Now let $x = m_1v$ and $y = m_2 \log u$ be perpendicular scales. The graph of the above relationship will then be a straight line whose cartesian equation is

$$y/m_2 = \left(\frac{\log b}{m_1}\right) x + \log$$

Coordinate paper with scales of this kind is called *semilogarithmic.*

Example: If $v = 3\cdot 2u$, then $\log v = u \log 2 + \log 3$. Figure 29-44 shows the graph when plotted on two-cycle semilogarithmic paper. Figure 29-45 shows the graph on a single-cycle paper.

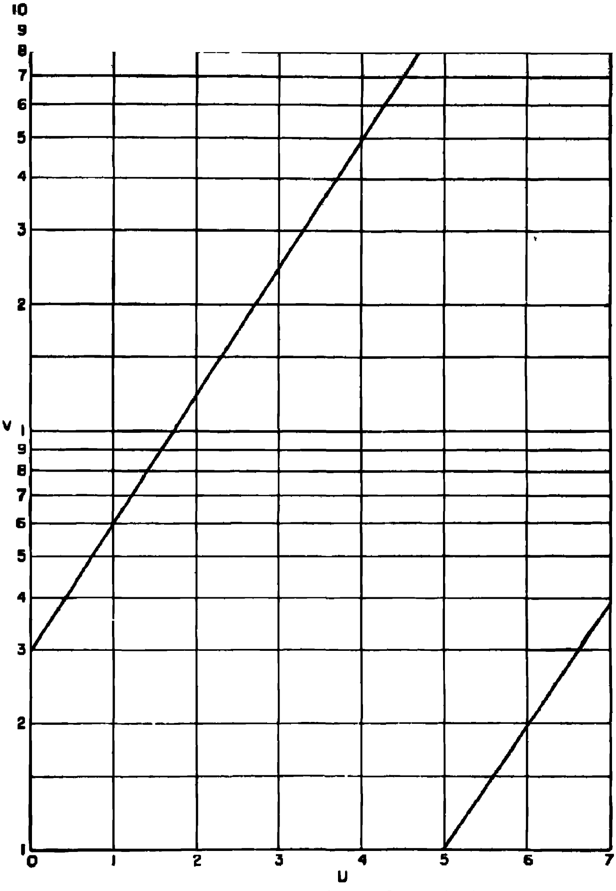

Fig. 29-44. $v = 3\cdot 2^u$ (two-cycle semilogarithmic paper).

Reciprocal. Equations of the type $v = u/(au + b)$ may be represented by a straight line on a coordinate paper whose perpendicular axes carry reciprocal scales. The equation $v = u/(au + b)$ may be written in the form $1/v = (b/u) + a$. If the x- and y-axes carry the scales $x = m(1/u)$ and $y = m(1/v)$, respectively, then the graph will be the straight line

$$y = bx + am$$

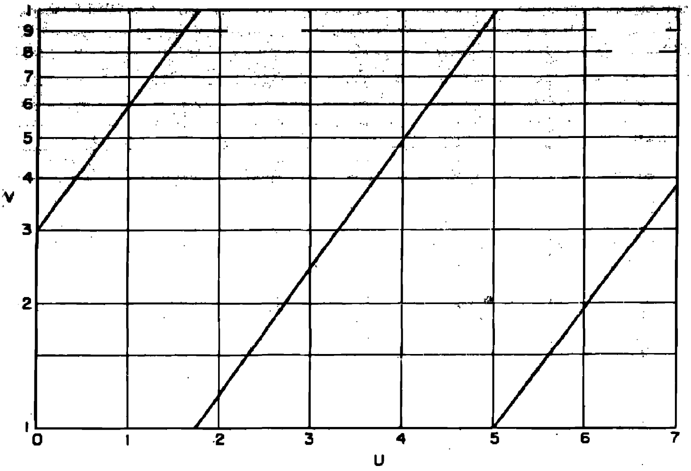

FIG. 29-45. $v = 3 \cdot 2^u$ (single-cycle semilogarithmic paper).

EXAMPLE: Sketch the equation $3u + 2v = uv$ on reciprocal coordinate paper. The equation may be written

$$\frac{2}{u} + \frac{3}{v} = 1$$

The graph is a straight line (Fig. 29-46).

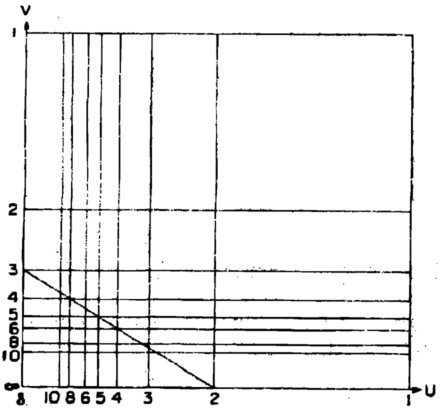

FIG. 29-46. $\frac{2}{u} + \frac{3}{v} = 1.$

Semisine. One axis on semisine paper carries a sine scale, the other a uniform scale. Figure 29-46*a* shows the plot of the equation 20 sin $v = u + 10$ on this type of paper.

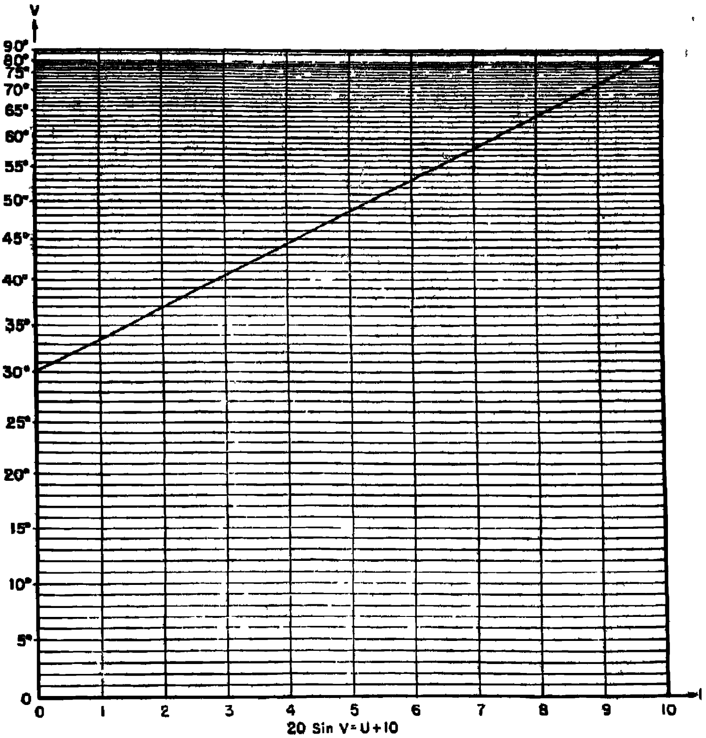

Fig. 29-46*a*.

Representation of a Relation between Three Variables. An equation in three variables of the form $f(u, v, w) = 0$ can be represented graphically by extending the methods used for graphing a two-variable relationship $\phi(u, v) = 0$. If one of the variables, say w, is held constant, then $\phi(u, v, c) = 0$, and the graph for each value of c held constant will be a curve or a straight line depending on the scales used.

To illustrate some of the possibilities, graph the relationship

$$\left(1 - \frac{S}{100}\right) = D$$

1. If uniform scales are used for S and P, D is represented by a family of curves (Fig. 29-47a).

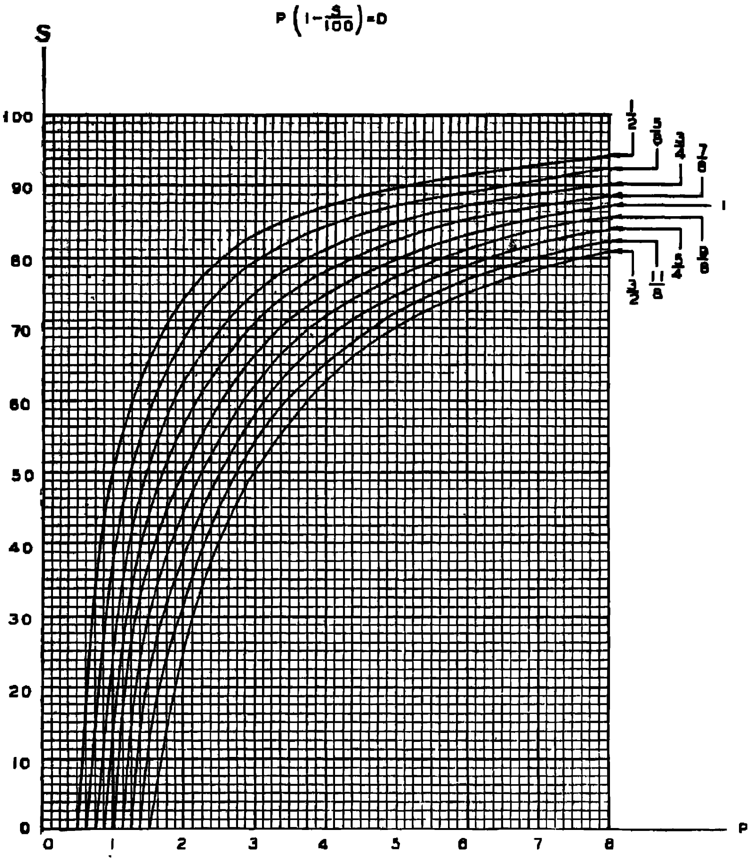

Fig. 29-47a.

2. If logarithmic scales are used for S and P, D is represented by a family of parallel straight lines (Fig. 29-47*b*).

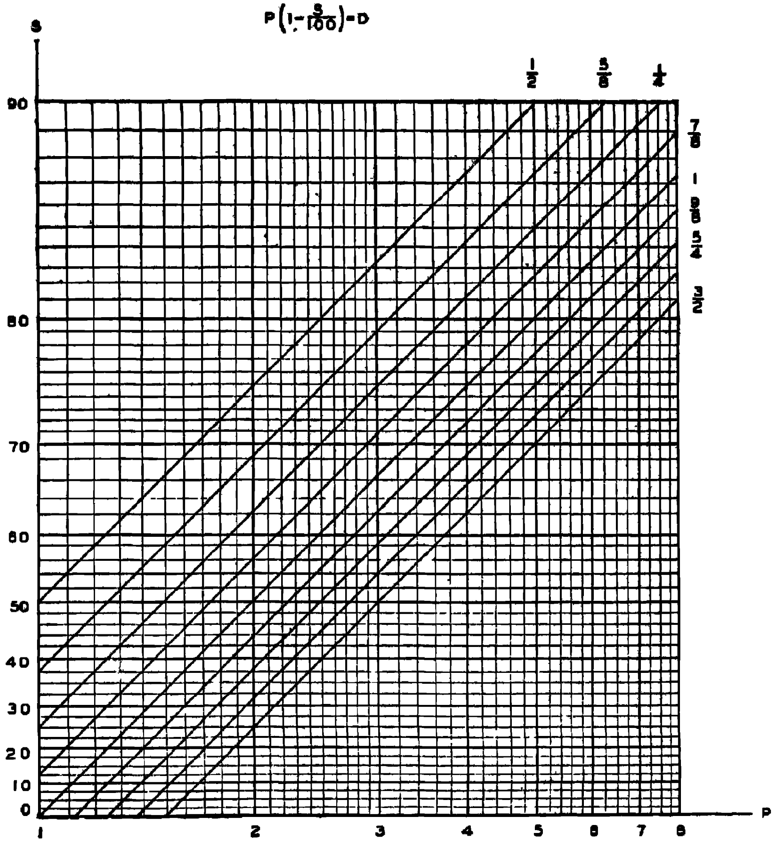

Fig. 29-47*b*.

3. If uniform scales are used for P and D, S is represented by a family of radiating straight lines (Fig. 29-47c).

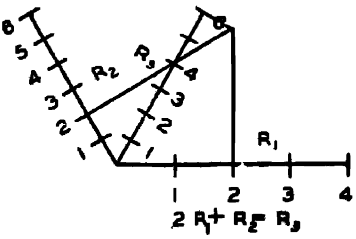

FIG. 29-50a.

Hexagonal Chart. This is a useful type of chart for the relation

$$f_1(u) + f_2(v) = f_3(w)$$

In Fig. 29-49*a* let OX and OY be perpendicular axes, and let OZ be the bisector of the angle between them. Lay off the scales $mf_1(u)$, $mf_2(v)$, and $(m/\sqrt{2})f_3(w)$ on the X-, Y-, and Z-axes, respectively. From any point P, draw perpendiculars to OX, OY, and OZ. The three points of intersection will give values of u, v, and w, satisfying the equation $f_1(u) + f_2(v) = f_3(w)$.

If the angle between OX and OY is 120 deg and OZ is the bisector of the angle, the modulus of each of the three scales will be the same (Fig 29-49*b*).

For examples see Figs. 29-50*a*, 29-50*b*.

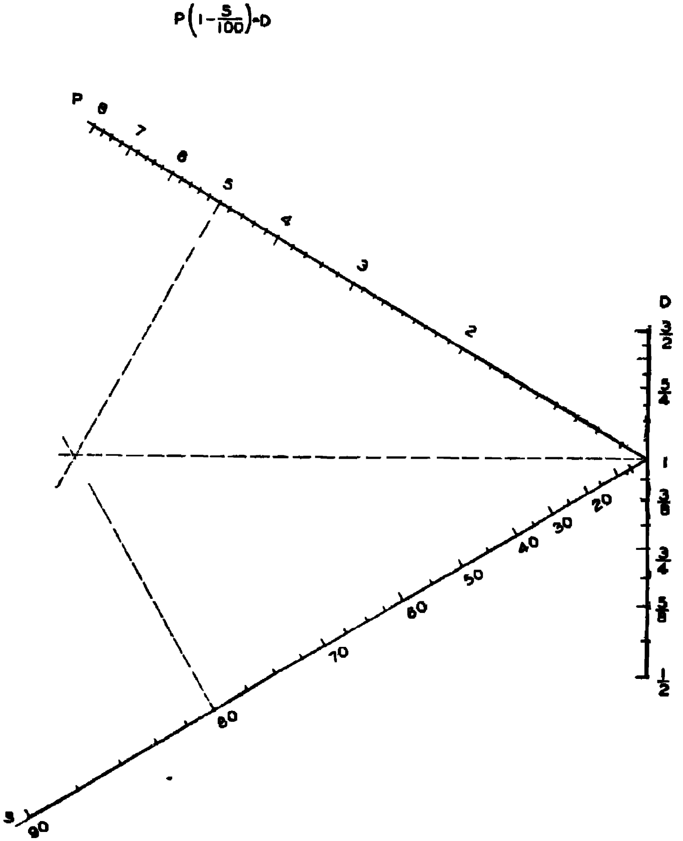

FIG. 29-50*b*.

QUADRATIC, CUBIC, AND BIQUADRATIC EQUATIONS

Quadratic Equation. Every quadratic equation in one variable can be put in the form

$$x^2 + Ax + B = 0 \tag{1}$$

This equation may be written

$$B = -Ax - x^2$$

If A and B are taken to be the coordinates of a point in a plane, the equation will represent a straight line for each real value of x. These lines are drawn in Fig. 29-51.

The complex roots of the equation may also be found graphically. Since the solution of Eq. (1) is known to be

$$x = -\tfrac{1}{2}A \pm \sqrt{\tfrac{1}{4}A^2 - B}$$

we may replace the quantity under the radical by $-k^2$; *i.e.*,

$$\tfrac{1}{4}A^2 - B = -k^2$$

or

$$B = \tfrac{1}{2}A^2 + k^2 \qquad (2)$$

where k is the coefficient of i ($i = \sqrt{-1}$) in the solution.

Equation (2) represents a family of parabolas for different values of k^2, where k^2 is the intercept on the b-axis (see Fig. 29-51).

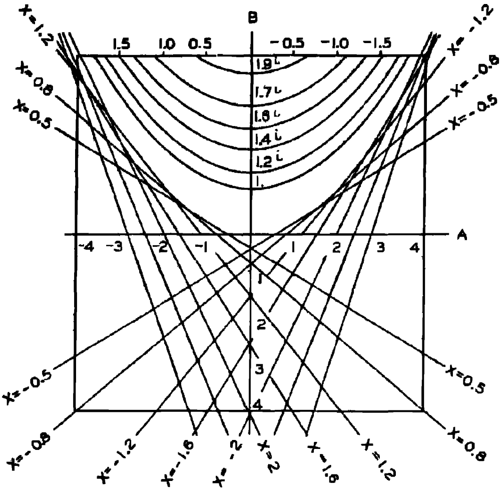

Fig. 29-51. $x^2 + Ax + B = 0$.

Cubic Equation. Every cubic equation can be written in the form

$$Y^3 + aY^2 + bY + c = 0 \qquad (1)$$

By making the substitution

$$Y = x - (a/3)$$

Eq. (1) may be written

$$x^3 + Ax + B = 0 \qquad (2)$$

where $A = b - \tfrac{1}{3}a^2$

$B = c - \tfrac{1}{3}ab + \tfrac{2}{27}{}^3$

Equation (2) may be written in the form

$$B = -Ax - x^3$$

which is the equation of a straight line for each real value of x plotted in the AB plane. The straight lines are shown in Fig. 29-52.

If Eq. (2) has complex roots, the three roots are of the form $2a$, $-a + ib$, and $-a - ib$, where $i = \sqrt{-1}$.

From Eq. (2)

$$A = b^2 - 3a^2 \qquad (3)$$

$$B = -2a^3 - 2ab^2 \qquad (4)$$

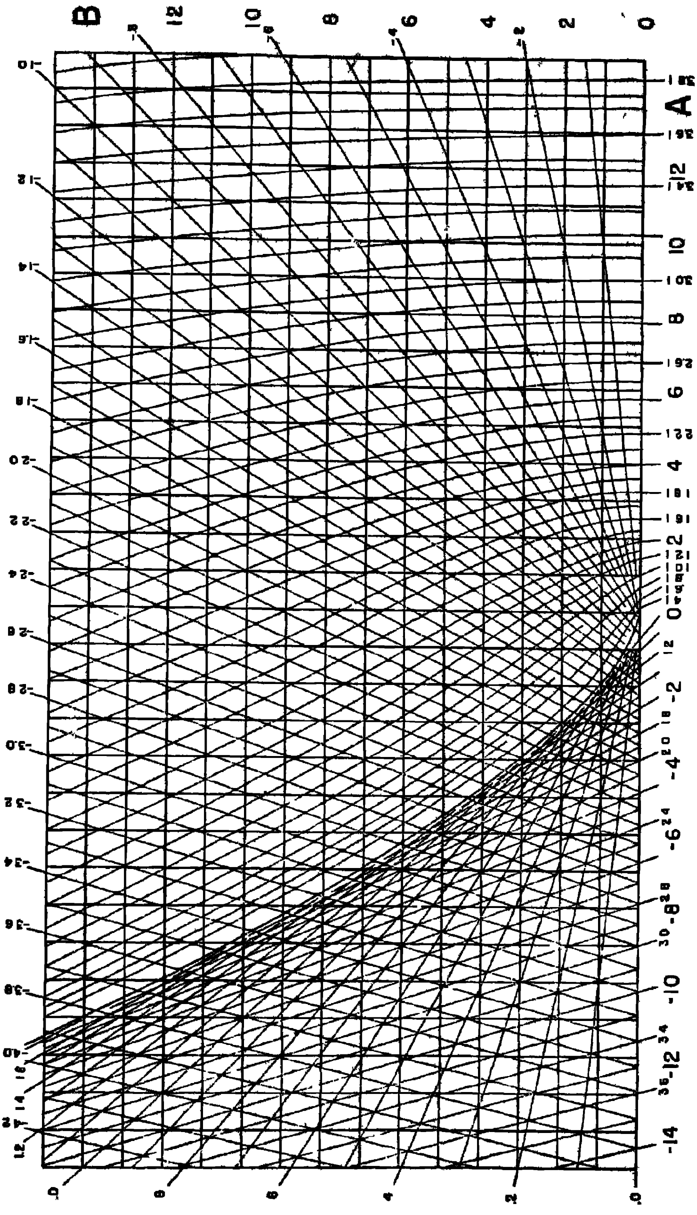

FIG. 29-52. $Y^3 + aY^2 + bY + c = 0$.

and from Eq. (3)

$$a = \pm\sqrt{\frac{b^2 - A}{3}} \tag{5}$$

Substituting the value of a in Eq. (5) into Eq. (4), we have

$$B^2 = -\tfrac{4}{27}(A - b^2)(A - 4b^2)^2 \tag{6}$$

Note that when $b = 0$, Eq. (6) becomes

$$B^2 = -\tfrac{4}{27}A^3$$

This curve forms the boundary between the region of all real roots and the region of complex roots. The completed chart is shown in Fig. 29-52.

Example 1: Find the roots of the cubic equation

$$x^3 - 13x + 12 = 0$$

$A = -13$, $B = 12$; then $x = 1, -4$, and 3.

Example 2: Solve the equation

$$x^3 - 15x - 126 = 0$$

Here $A = -15$ and $B = -126$. Since only positive values of B from 0 to 15 are on the chart, let $x = -3z$, for example. Then the equation becomes

$$z^3 - 1.67z + 4.7 = 0$$

From Fig. 29-52 we read

$$z = -2,\ 1 \pm 1.13i$$

therefore $x = 6,\ -3 \pm 3.39i$.

Example 3: Solve the equation

$$y^3 - 3y^2 + 9y + 13 = 0$$

Let $y = x + 1$. Then the resulting equation is

$$x^3 + 6x + 20 = 0$$

As in Example 2, $B = 20$ is not on the chart. Now let $x = 2z$. Then the equation becomes

$$z^3 + 1.5z + 2.5 = 0$$

Hence $A = 1.5$ and $B = 2.5$.
From the chart we read

$$z = -1,\ 0.5 \pm 1.5i$$

and $x = -2,\ 1 \pm 3i$

Therefore $y = -1,\ 2 \pm 3i$

Biquadratic Equation. The equation of the biquadratic is

$$x^4 + Ax^3 + Bx^2 + Cx + D = 0 \tag{1}$$

This equation may be written as

$$(x^2 + ax + b)(x^2 + cx + d) = 0$$

where $A = a + c$
$B = b + d + ac$
$C = ad + bc$
$D = bd$

Let $K = ac$ and $L = b + d$; then $B = L + K$.
From the equations $L = b + d$ and $D = bd$, we obtain

$$b = \tfrac{1}{2}L + \tfrac{1}{2}\sqrt{L^2 - 4D}$$

and

$$d = \tfrac{1}{2}L - \tfrac{1}{2}\sqrt{L^2 - 4D}$$

From the equations $A = a + c$ and $K = ac$, we obtain

$$a = \tfrac{1}{2}A + \tfrac{1}{2}\sqrt{A^2 - 4K}$$

and

$$c = \tfrac{1}{2}A - \tfrac{1}{2}\sqrt{A^2 - 4K}$$

Substituting the values of a, b, c, and d in the equation $C = ad + bc$, together with the relation $K = B - L$, we obtain the cubic equation

$$L^3 - BL^2 + (AC - 4D)L + 4BD - C^2 - A^2D \quad 0 \qquad (2)$$

By letting $L = Z + \frac{1}{3}B$, the last equation becomes

$$Z^3 + (AC - 4D - \tfrac{1}{3}B^2)Z + \tfrac{1}{3}(ABC + 8BD - \tfrac{2}{9}B^3 - 3C - 3A^2D) = 0$$

It is to be noted that the coefficients of cubic Eq. (2) are obtained directly from the coefficients of the original biquadratic Eq. (1).

The values of Z are obtained from the cubic chart (Fig. 29-52), and $b + d$ is obtained from the relation $L = b + d = Z + \frac{1}{3}B$. The numerically greatest of the real values of $Z + \frac{1}{3}B$ will always give real values of b and d.

Since $b + d = L$ and $bd = D$, then b and d are roots of the equation

$$u^2 - Lu + D = 0$$

and are found from the quadratic chart (Fig. 29-51).

Any method for obtaining the exact values of the roots of a biquadratic equation is laborious. However, making use of the resultant cubic and its chart reduces the time element to a minimum. The following example will illustrate the process of transforming an equation.

Example: Solve for the roots of the equation

$$6x^2 - 8x - 3 \quad 0$$

Here $A = 0$, $B = -6$, $C = -8$, and $D = -3$. Therefore $Z = 0$, and $L = -2$. Then $u^2 + 2u - 3 = 0$, and $u = 3, -1$; *i.e.*, $b = -3$, and $d = -1$. $k = -6 + 2 = -4$, and $ac = -4$; $a + c = 0$. Therefore $a = \pm 2$, and $c = \mp 2$. The biquadratic reduces to

$$(x^2 + 2x - 3)(x^2 - 2x + 1) = 0$$

or

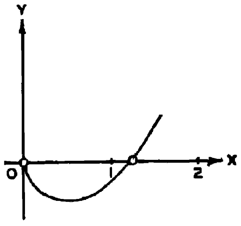
$$(x^2 - 2x - 3)(x^2 + 2x + 1) = 0$$

Hence $x = 1, -3, 1, 1$; or $x = -1, 3, -1, -1$. The first set of values does not satisfy but the second set does. Therefore $x = -1, -1, -1, 3$.

SOLUTION OF EQUATIONS CONTAINING A SINGLE VARIABLE

It is often necessary to solve an equation of the form $f(x) = 0$, where the exact solution cannot be found by any known method. An approximate solution may be found by one of several methods. Three of these methods are as follows:

1. Sketch the curve $y = f(x)$, and estimate where the curve crosses the x-axis.



$e^x - 2x - 1 = 0$
FIG. 29-53.

Example: Solve the equation

$$e^x - 2x - 1 = 0$$

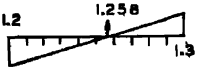
Sketch the curve $y = e^x - 2x - 1$ from the following table of values (Fig 29-53).

x	y	x	y	x	y
0	0	1.1	−0.2	1.21	−0.07
1	−0.28	1.2	−0.08	1.25	−0.01
2	+2.30	1.3	+0.07	1.26	+0.005

The first table shows that the value of x is between $x = 1$ and $x = 2$.

The second table shows that the value of x is between $x = 1.2$ and $x = 1.3$.

Now magnify the scale between $x = 1.2$ and $x = 1.3$, and draw a line from point (1.2, −0.08) to point (1.3, 0.07). The point where this line crosses the x-axis is a good approximation. The value is approximately 1.258 (Fig. 29-54).



$e^x - 2x - 1 = 0$
FIG. 29-54.

2. *a*. If scales are available, divide the function $f(x)$ into two parts, *e.g.*, $f_1(x) = f_2(x)$, and lay off stationary scales for $f_1(x)$ and $f_2(x)$. Locate on these scales where the markings opposite each other have the same value (Fig. 29-55).

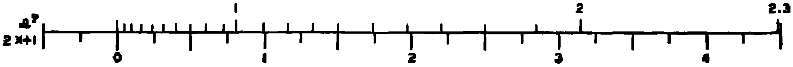


FIG. 29-55. $e^x - 2x - 1 = 0$.

EXAMPLE: Solve $e^x = 2x + 1$.

b. Instead of stationary adjacent scales, use perpendicular scales. This amounts to sketching each of the curves $y = e^x$ and $y = 2x + 1$ on the same diagram. At the point or points of intersection drop an ordinate to the x-axis. This value of x will be an approximate answer (Fig. 29-56).

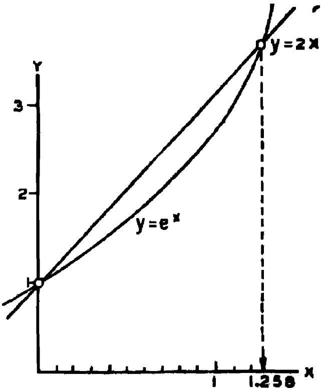

FIG. 29-56. $e^x - 2x - 1 = 0$.

3. Lay off an e^y scale on the y-axis and a uniform scale on the x-axis. The sketch of the equation $e^y = 2x + 1$ will be a straight line.

If perpendicular axes are drawn on a sheet of transparent paper and their intersection is moved along the straight line, always keeping the respective axes parallel, until the numbers at both feet of the moving axes are the same, this number will be the required answer (Fig. 29-57).

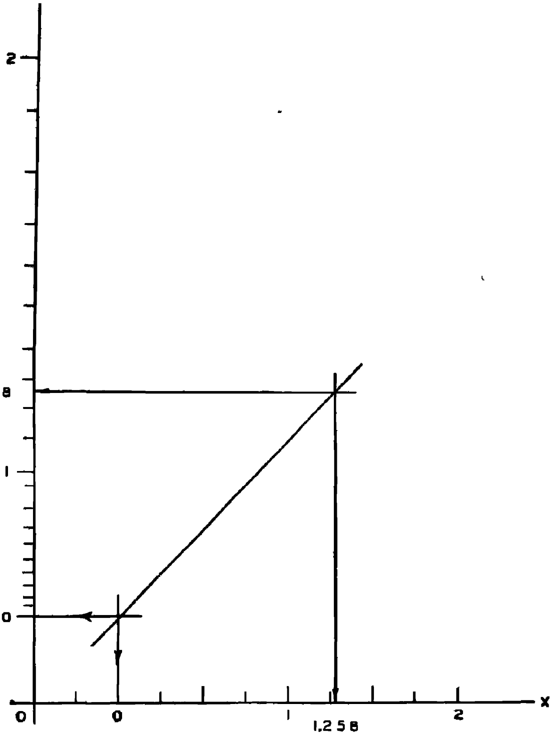

FIG. 29-57. $e^x - 2x - 1 = 0$.

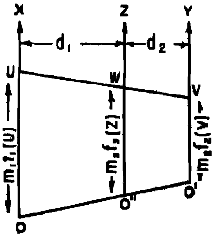
NOMOGRAPHIC OR ALIGNMENT CHARTS

Types. The fundamental principles involved in the construction of a nomographic, or alignment, chart consists of the representation of the relationship between three variables of the form $f(u, v, w) = 0$ by means of three scales along three axes (straight or curved) in such a way that a straight line cuts the three scales in values of u, v, and w, satisfying the equation $f(u, v, w) = 0$. Some of the most common methods of constructing charts are described below. In the notation used, $f_1(u)$ is any function of u alone, $f_2(v)$ is any function of v alone, etc.



$f_1(u) + f_2(v) = f_3(w)$
FIG. 29-58.

1. $f_1(u) + f_2(v) = f_3(w)$

a. Draw two parallel lines OX and $O'Y$ any distance apart, and on these axes construct the scales $x = m_1f_1(u)$ and $y = m_2f_2(v)$, measured from convenient points 0 and 0′, respectively, where m_1 and m_2 are convenient moduli.

b. Draw a third line $O''Z$ parallel to OX and $O'Y$ such that

$$\frac{\text{Distance } (d_1) \text{ from } OX \text{ to } O''Z}{\text{Distance } (d_2) \text{ from } O''Z \text{ to } O'Y} = \frac{m_1}{m_2}$$

c. Determine a starting point for the graduations of the w scale. It is convenient to draw a line from a value u_0 on the u scale to a value of v_0 on the v scale. This line will cut the w scale at a value w_0, which is computed from the equation

$$f_1(u_0) + f_2(v_0) = f_3(w_0)$$

Now take any other pair of values of u and v, and on the w scale mark the corresponding value of w, say w_1.

d. The equation of the w scale is

$$z = \frac{m_1 m_2}{m_1 + m_2} f_3(w)$$

e. Move the z scale in (*d*) along the z-axis until the number w_0 on the scale is opposite the number w_0 already calculated by (*c*). A check on the work up to now reveals that w_1 on the scale is opposite the number w_1 already calculated by (*c*).

f. If we have a scale of $f(u)$ constructed as in Figs. 29-31*a* to 29-31*k*, it is easy to make the check suggested in (*e*) by using compasses to take off measurements.

EXAMPLE: Construct a nomogram for the equation $2U + W = 10 \log V$. Let the variables range as follows: V from 1 to 10, U from 0 to 5, and W from 0 to 10.

If it is desired to have the W scale in the center, rewrite the equation as

$$10 \log V - 2U = W$$

The scales are $m_1(10 \log V)$, $m_2(2U)$, and $m_3(W)$ where $m_3 = m_1m_2/(m_1 + m_2)$. The V and U scales will be constructed in opposite directions because of the negative sign. The length of the chart is to be 10 in. Therefore, $m_1 = 1$, $m_2 = 1$, and $m_3 = \frac{1}{2}$. The scales to be constructed are $10 \log V$, $2U$, and $\frac{1}{2}W$. Since $(d_1/d_2) = (m_1/m_2) = 1$, $d_1 = d_2$, and the W scale is midway between. When $U = 0$ and $V = 1$, $W = 0$; and when $U = 0$ and $V = 10$, $W = 10$. The completed chart is shown in Fig. 29-59. When $V = 8$ and $W = 3$, $U = 3.01$.

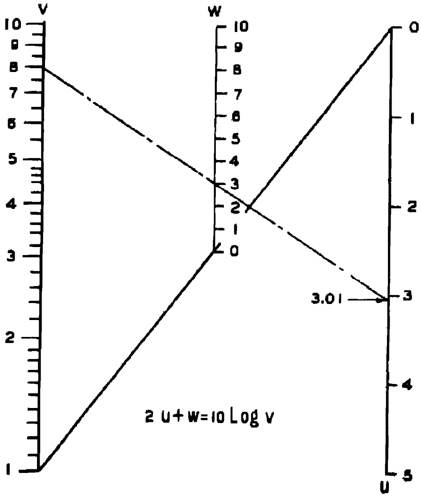


FIG. 29-59.

A chart for the equation of net radiation $q/A = \sigma(T_1^4 - T_2^4)$ is shown in Fig. 29-59*a*.

2. $$f_1(u) \cdot f_2(v) = f_3(w)$$

Any equation in this form can be put into the form of (1) by taking logarithms of both sides. Thus

$$\log f_1(u) + \log f_2(v) = \log f_3(w)$$

This equation then takes the form

$$F_1(u) + F_2(v) = F_3(w,$$

and the method of (1) applies.

Example: Construct a nomogram for the equation

$$E = \pi B \sin^2 \theta$$

where E is illumination in lumens per square centimeter, B is brightness in candles per square centimeter, and θ is the solid angle subtended by the source.

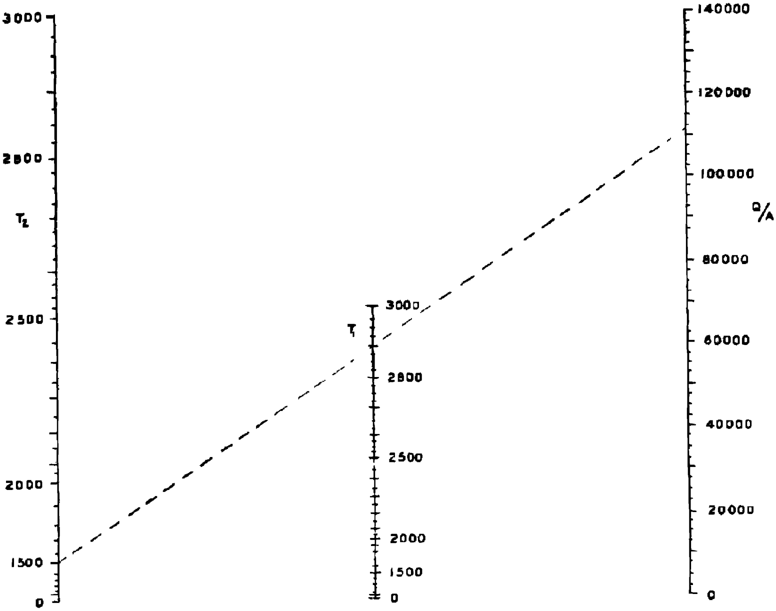

FIG. 29-59a. $b/A = \sigma(T_1^4 - T_2^4)$.

Taking logarithms of both sides of the equation, we have

$$\log E = \log B + 2 \log \sin \theta + \log \pi$$

The ranges of the variables are B from 1 to 100, θ from 1 to 16 deg, and E from 0.01 to 20. It is desired to have the B and θ scales each of length 8 in. The scales are $m_1 \log B$, m_2 $(2 \log \sin \theta)$, and $m_3 \log E$.

Since $\log 100 = 2$ and $\log 1 = 0$, $m_1 = 4$. Since $\log \sin 16$ deg $= -0.5597$ and $\log \sin 1$ deg $= -1.7581$,

$$m_2(-1.1194 + 3.5162) = 8 \qquad \text{or } m_2 = 3.34$$

$(d_1/d_2) = (m_1/m_2) = 4/3.34$. Let the distance between the B- and θ-axes

$$(d_1 + d_2) = 7.34 \text{ in.},$$

then $d_1 = 4$ in., and $d_2 = 3.34$ in. The equations of the scales are $4 \log B$, $6.68 \log \sin \theta$, and $[4(3.34)/(4 + 3.34)] \log E = 1.82 \log E$. The completed chart is shown in Fig. 29-60.

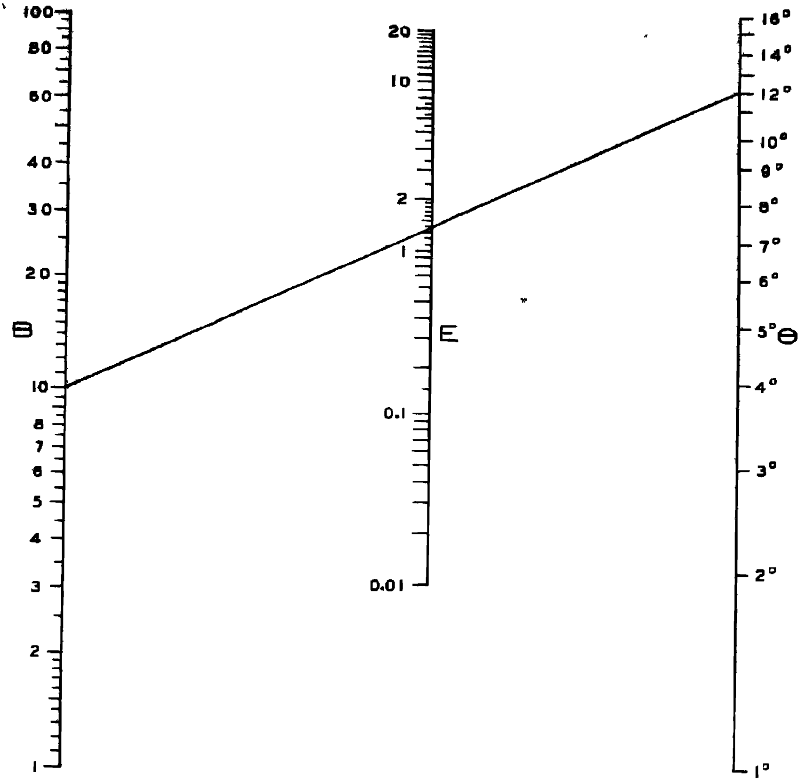

FIG. 29-60. $E = \pi B \sin^2 \theta$.

EXAMPLE: Construct a nomogram for the equation

$$P\left(1 - \frac{S}{100}\right) = D$$

where D varies in $\frac{1}{8}$ units from $\frac{3}{2}$ to $\frac{1}{2}$, P varies from 1 to 8, and S varies from 10 to 90. Taking logarithms of both members of the equation we have

$$\log D = \log P + \log\left(1 - \frac{S}{100}\right)$$

The completed chart is shown in Fig. 29-61.

3. $$[f_1(u)]^{f_2(v)} = f_3(w)$$

Taking logarithms of both sides, the equation then takes the form

$$f_2(v) \log f_1(u) = \log f_3(w)$$

Taking logarithms again of both sides, the equation becomes

$$\log f_2(v) + \log \log f_1(u) = \log \log f_3(w)$$

which, again, is of the form

$$F_1(u) + F_2(v) = F_3(w)$$

4. $$f_1(u) + f_2(v) + f_3(w) + \cdots = f_n(t)$$

or

$$f_1(u) \cdot f_2(v) \cdot f_3(w) \cdots = f_n(t)$$

This equation is merely an extension of (1), and the method of charting is an extension of the method employed in charting (1). For example, consider the case of four variables in an equation of the form $f_1(u) + f_2(v) + f_3(w) = f_4(t)$.

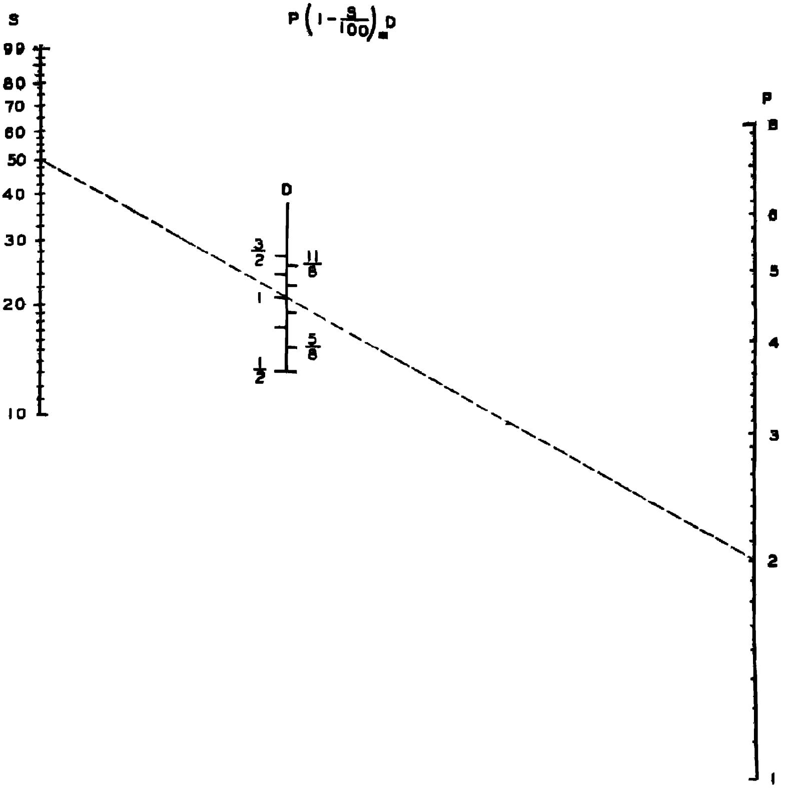

Fig. 29-61

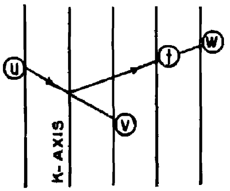

Fig. 29-62

$f_1(u) + f_2(v) + f_3(w) = f_4(t)$.

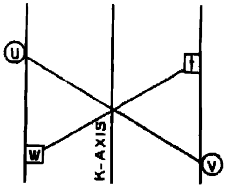

Fig. 29-63.

$f_1(u) + f_2(v) + f_3(w) = f_4(t)$.

Let $f_1(u) + f_2(v) = k$, then $k + f_3(w) = f_4(t)$. Each of these equations is in the form of (1), and each can be charted by means of three parallel scales, but the k scale need not be graduated (Figs 29-62, 29-63).

The first type is illustrated by the following charts (Fig. 29-64):

$$W = 12PA^4/(64 \times 29 \times 10^6T^3)$$

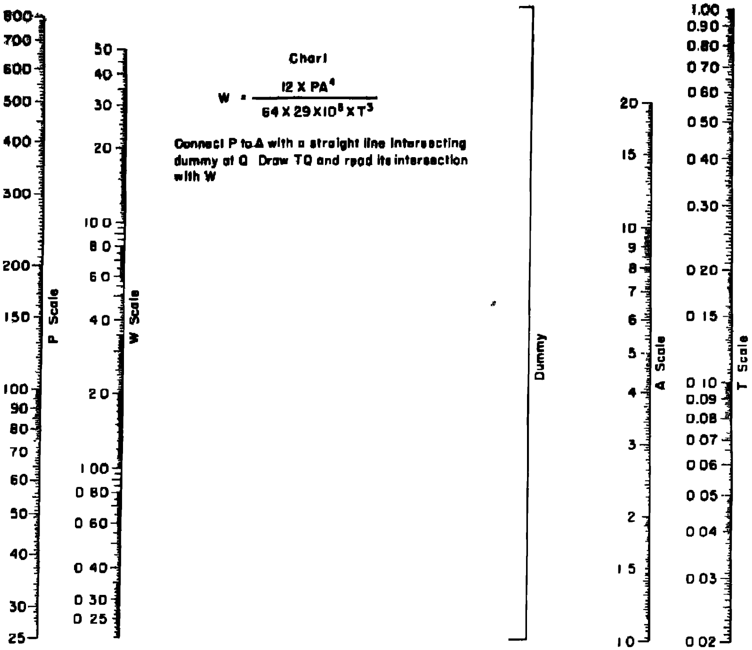

FIG. 29-64.

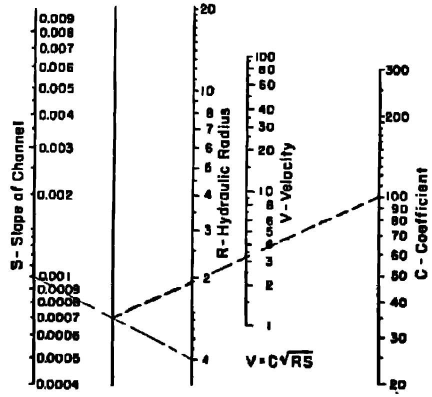

FIG. 29-65.

Chezy formula for the velocity of flow of water, $V = C\sqrt{rs}$ (Fig. 29-65),

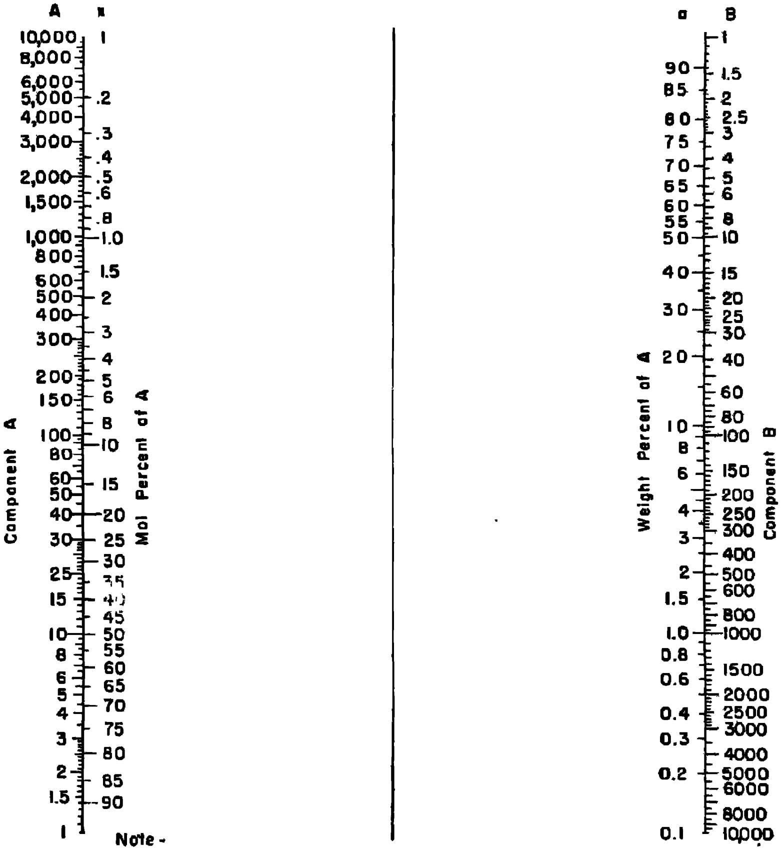
Nomogram on mol per cent—weight per cent (Fig. 29-66).

The second type is illustrated by charts for solution of triangles by the law of tangents (Fig. 29-67), draft correction for salt and fresh-water-going vessels (Fig. 29-68), and the equations $(u_1/u_2) = (v_1/v_2)$ (Fig. 29-69*a*) and $x = v_{0t} \cos \beta$ (Fig. 29-69*b*).

$$5. \qquad f_1(u) - f_2(v) = f_3(w) - f_4(t) \qquad \text{or} \qquad f_1(u)/f_2(v) = f_3(w)/f_4(t)$$

The first equation is obviously of the form (1), and the second equation is immediately transformed into the first form by taking logarithms of both members of the equation. However, sometimes it is convenient to apply the following scheme:

If the range of variables is such that we can use the modulus m_1 for each of the terms $f_1(u)$ and $f_2(v)$ and m_2 for each of the terms $f_3(w)$ and $f_4(t)$, lay off the scales $x = m_1f_1(u)$, $y = m_1f_2(v)$, $z = m_2f_3(w)$, and $q = m_2f_4(t)$, as indicated in Fig. 29-70. To read such a chart, join given values of u and v, and through a given value of w, draw a parallel line cutting the q scale at the value of t which satisfies the original equation.



Note -
A line drawn between molecular weights of A and B will give a turning point on the center line. Any other line drawn through this point will connect weight and mol percents of component A

Relation $\frac{A}{B} = \frac{\frac{100-x}{x}}{\frac{100-a}{a}}$

FIG. 29-66.

Figure 29-71 shows a chart for the relation $u_1v_1 = u_2v_2$.

6. $$f_1(u) + f_2(v) = f_3(w)/f_4(t)$$

Fig. 29-67.

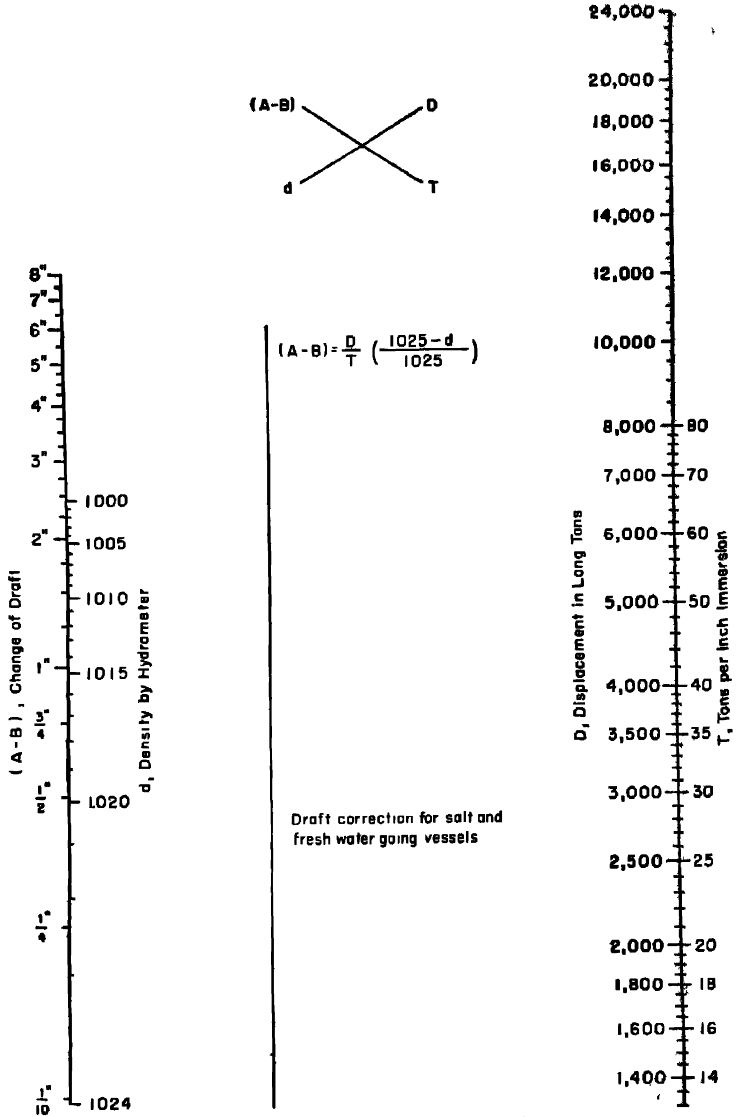

Fig. 29-68 $A - B = \frac{D}{T}\left(\frac{1.025 - d}{1.025}\right)$.

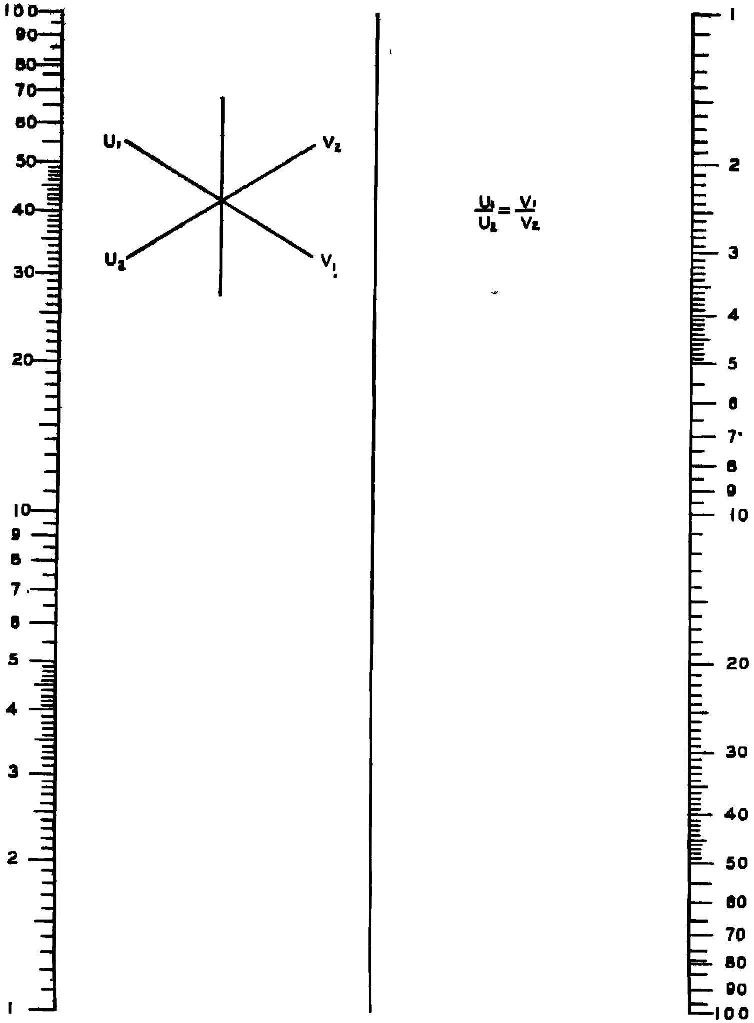

Fig. 29-69a.

Scales are laid off on two parallel axes, OX and $O'Y$, drawn in opposite directions, and the intersecting axis OO'. Let the length of OO' be K where K is any convenient length. Lay off the scales $m_1f_1(u)$ and $m_3f_3(w)$ on OX, $m_1f_2(v)$ on $O'Y$, and $m_4f_4(t)$ on OO', as indicated in Fig. 29-72.

The moduli are related by the equation

$$m_1/K = m_3/m_4$$

Any pair of parallel index lines (u, v) and (w, t) will cut the axes in values of u, v, w, and t, satisfying the equation.

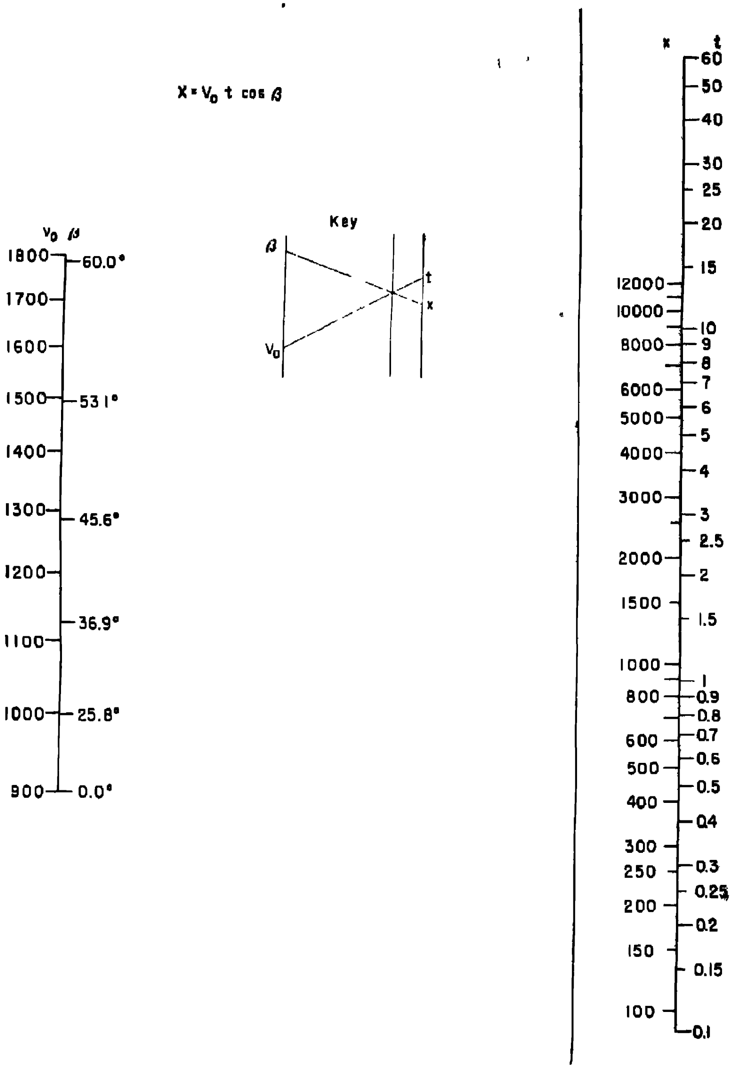

Fig. 29-69b.

7.
$$f_1(u) - f_2(v) = f_3(w)/f_4(t)$$

The chart for this equation is the same as that above except that the axes OX and $O'Y$ are drawn in the same direction. Again

$$m_1/K_4 = m_3/m_4$$

8.
$$\frac{1}{f_1(u)} + \frac{1}{f_2(v)} = \frac{1}{f_3(w)}$$

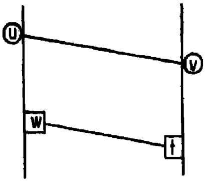

FIG. 29-70. $f_1(u) - f_2(v) = f_3(w) - f_4(t)$ or $f_1(u)/f_2(v) = f_3(w)/f_4(t)$.

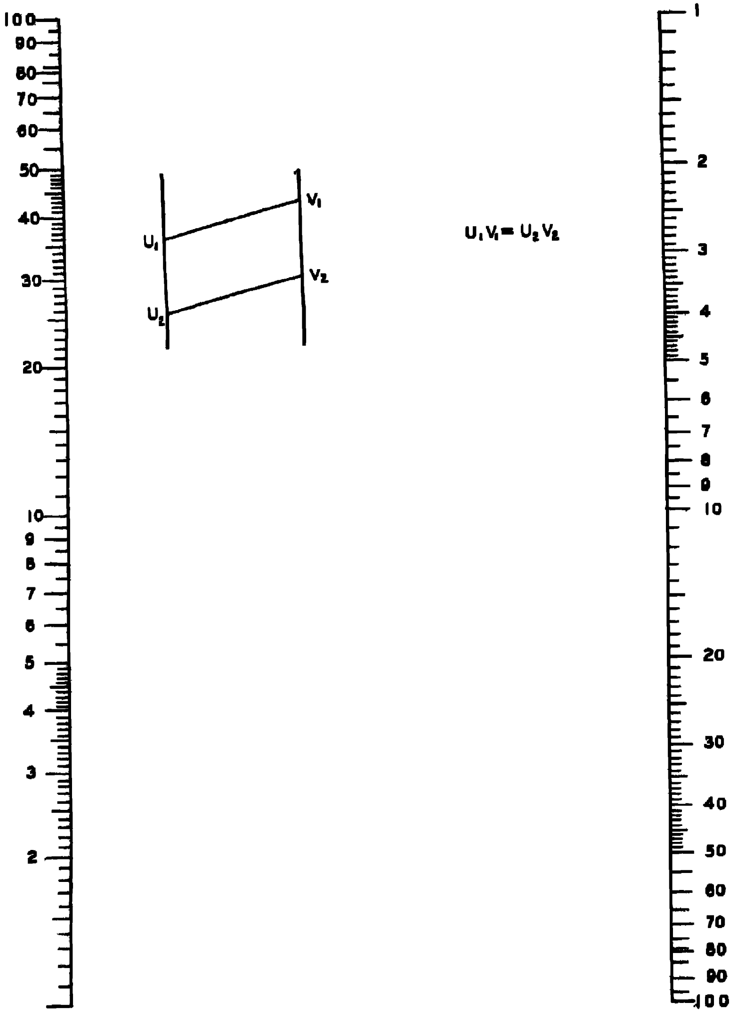

FIG. 29-71.

Draw three intersecting axes OX, OY, and OZ making angles of 60 deg with each other. On OX, OY, and OZ lay off the scales $m_1f_1(u)$, $m_1f_2(v)$, and $m_1f_3(w)$, respectively (Fig. 29-77). An index line cutting the axes in two of the variables will cut the other axis at the value of the third variable, satisfying the equation

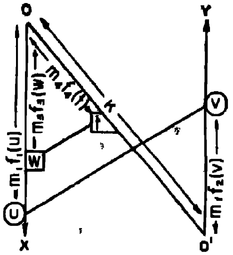

Fig. 29-72 $f_1(u) + f_2(v) = \frac{f_3(w)}{f_4(t)}$

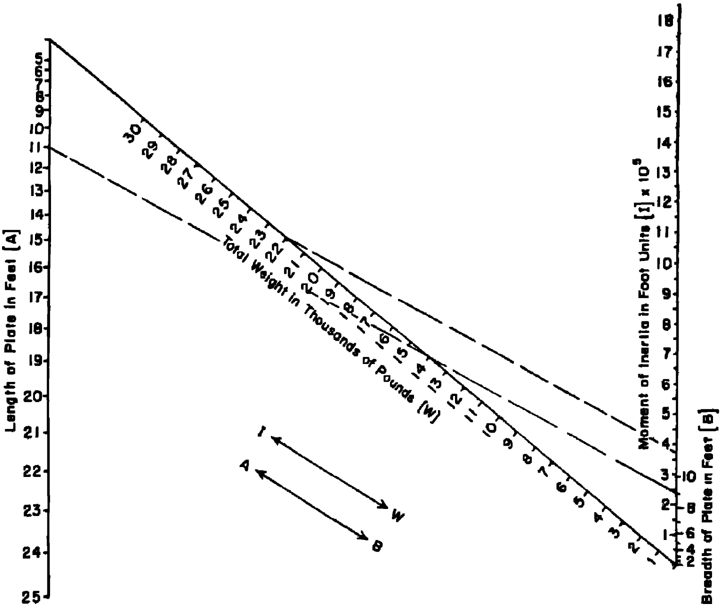

Fig. 29-73. Moment of inertia of a rectangular plate.

$$[1/f_1(u)] + [1/f_2(v)] = [1/f_3(w)]$$

It is to be noticed that negative values will be laid off in opposite directions.

9. $$\frac{1}{f_1(u)} + \frac{1}{f_2(v)} + \cdots = \frac{1}{f_n(t)}$$

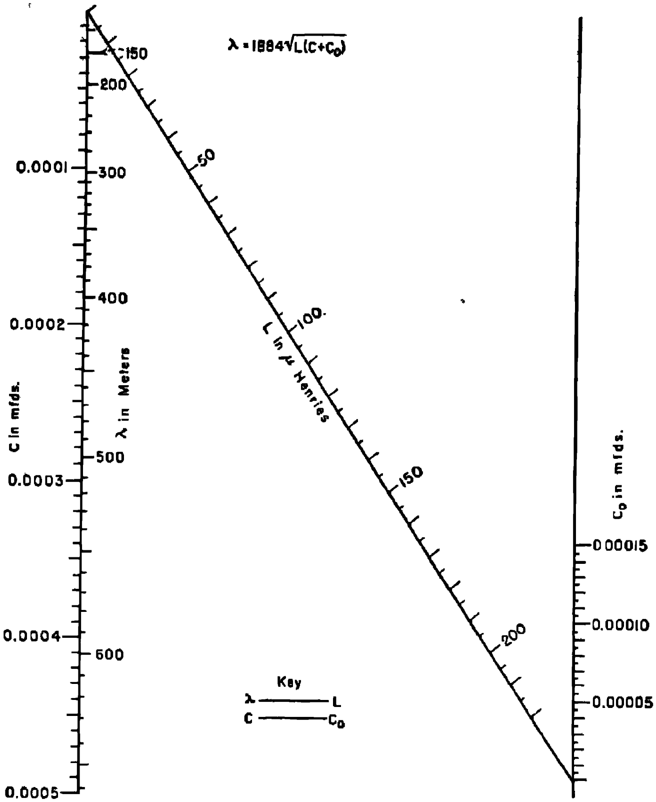

FIG. 29-74.

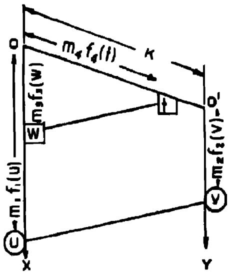

FIG. 29-75. $f_1(u) - f_2(v) = \dfrac{f_3(w)}{f_4(t)}$.

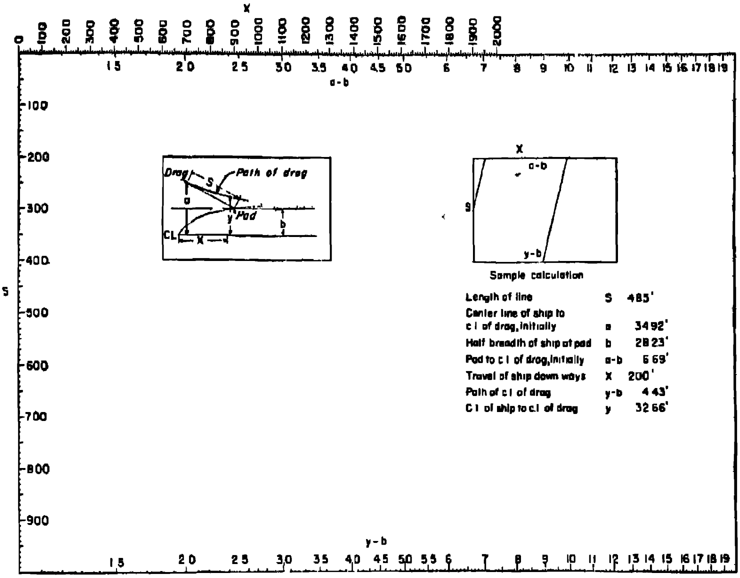

Sample calculation

Length of line	S	485'
Center line of ship to c l of drag, initially	a	34 92'

Pad to c l of drag, initially	a-b	6 69'
Travel of ship down ways	X	200'
Path of c l of drag	y-b	4 43'
C l of ship to c.l of drag	y	32 66'

FIG. 29-76. Path of drag in ship launching.

The method of charting this equation is an extension of the method employed in the previous case. Consider the case of four variables

$$[1/f_1(u)] + [1/f_2(v)] + [1/f_3(w)] = [1/f_4(t)]$$

If we introduce an auxiliary variable Q, we can write

$$\frac{1}{f_1(u)} + \frac{1}{f_2(v)} = \frac{1}{Q} \qquad \text{and} \qquad \frac{1}{Q} + \frac{1}{f_3(w)} = \frac{1}{f_4(t)}$$

Chart each of these equations with a common Q scale which need not be graduated (Fig. 29-79).

10. $$f_1(u) + f_2(v) \cdot f_3(w) = f_4(w)$$

Draw two parallel axes OX and $O'Y$, and let K be the length of OO'. On OX lay off the scale $m_1 f_1(u)$, and on $O'Y$ lay off the scale $m_2 f_2(v)$ (Fig. 29-81). Construct the scale

$$x_1 = -\frac{m_1 K}{m_1 f_3(w) + m_2} f_3(w)$$

along the axis OO', and the scale

$$y_1 = \frac{m_1 m_2}{m_1 f_3(w) + m_2} f_4(w)$$

parallel to OX.

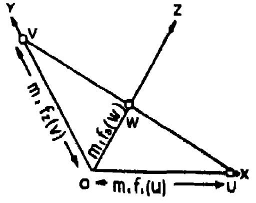

FIG. 29-77. $\frac{1}{f_1(u)} + \frac{1}{f_2(v)} = \frac{1}{f_3(w)}$.

Each value of w determines values of x_1 and y_1, *i.e.*, the position of a point (x_1, y_1) and the series of points determines a w scale on a curve or straight line. Any index line will cut the three scales in values of u, v, and w, satisfying the equation

$$f_1(u) + f_2(v) \cdot f_3(w) = f_4(w)$$

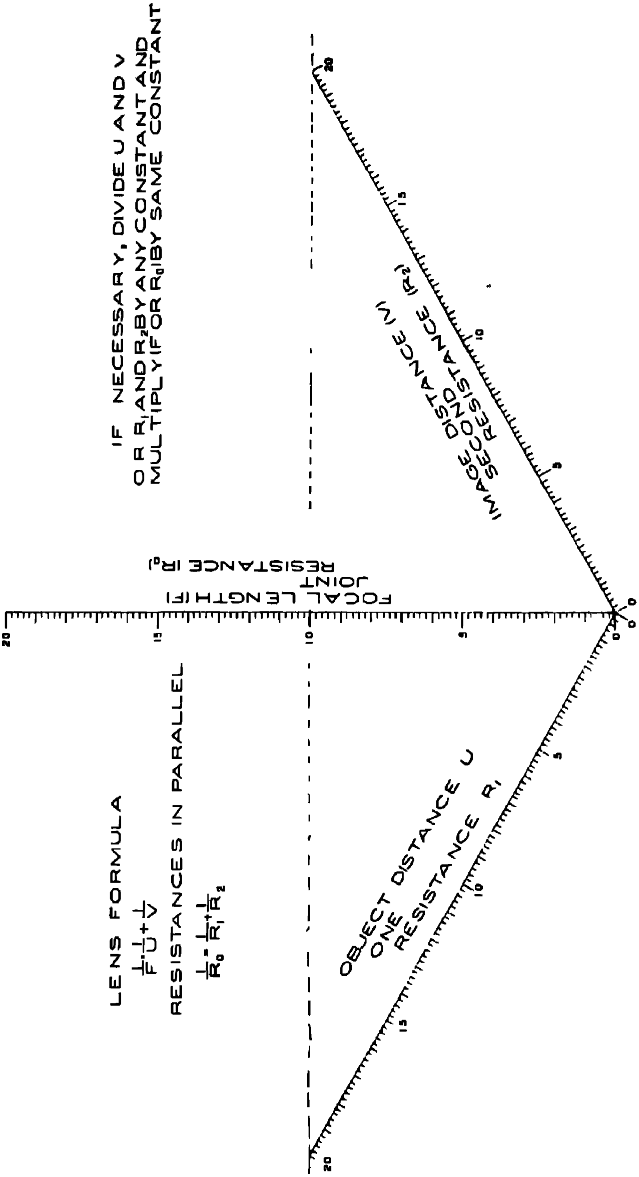

Fig 29-78. $\frac{1}{F} = \frac{1}{u} + \frac{1}{v}$.

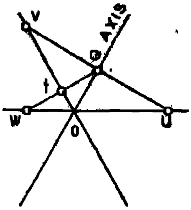

FIG. 29-79. $\dfrac{1}{f_1(u)} + \dfrac{1}{f_2(v)} + \cdots = \dfrac{1}{f_n(t)}$.

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R_n}$$

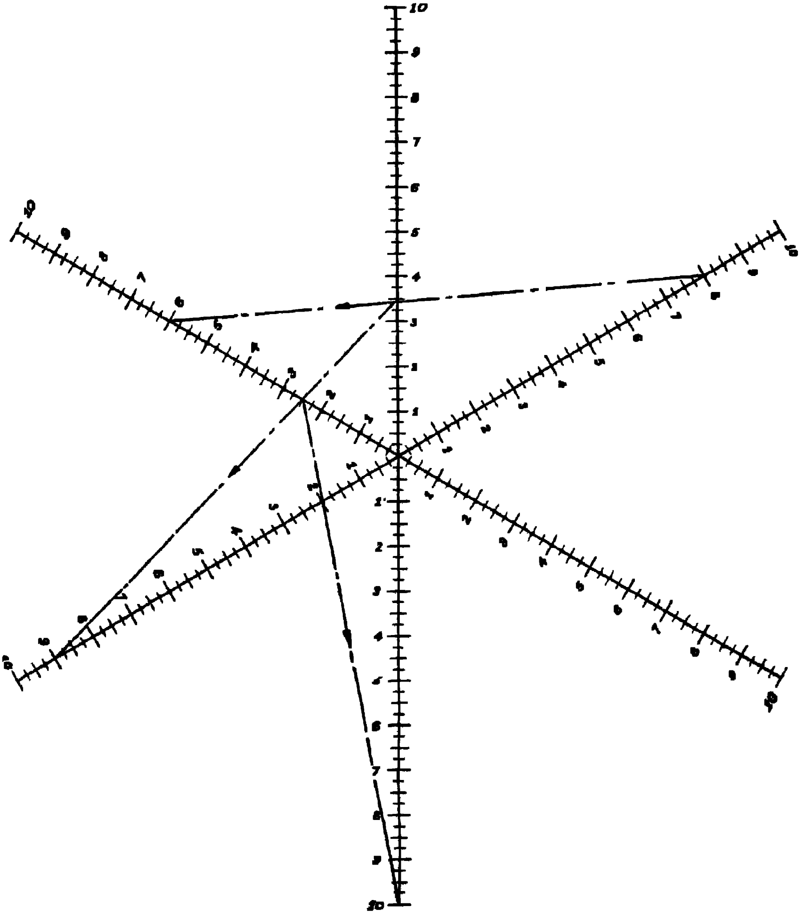

FIG. 29-80

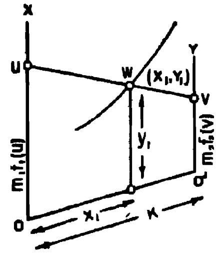

FIG. 29-81. $f_1(u) + f_2(v) \cdot f_3(w) = f_4(w)$.

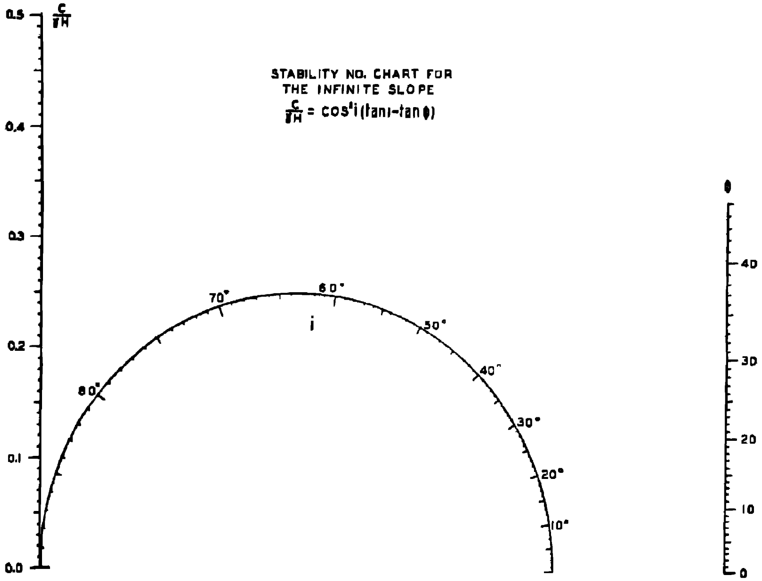

FIG. 29-82.

Charts of this type are illustrated by the following examples:

Example 1. Stability number for the infinite slope in a homogeneous soil

$$\frac{C}{\gamma H} = \cos^2 i(\tan i - \tan \phi)$$

where C = cohesion of soil, lb/sq ft
H = depth of element
i = slope of ground surface
ϕ = angle of internal friction of soil

The dimensionless quantity $C/\gamma H$ is the stability number. This equation may be written

$$C/\gamma H + \tan \phi \cos^2 i = \cos^2 i \tan i$$

and is in the form $f_1(u) + f_2(v)f_3(w) = f_4(w)$.
The scales are $x = m_1\,(C/\gamma H)$, $y = m_2 \tan \phi$,

$$x_1 = \frac{m_1 K}{m_1 \cos^2 i + m_2} \qquad \frac{m_1 m_2}{m_1 \cos^2 i + m_2} \cos^2 i \tan i$$

Let $m_1 = 15$, $m_2 = 5$, and $K = 10$.

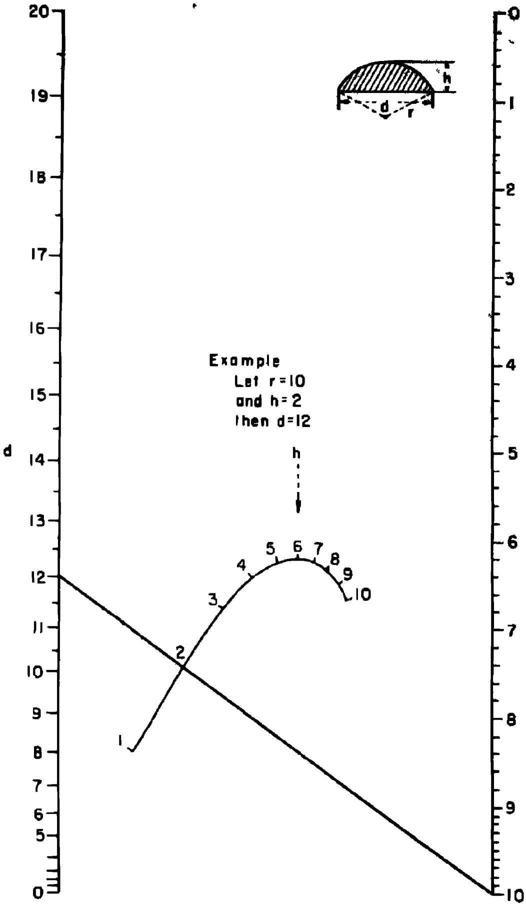

Fig. 29-83. $d^2 = 8rh - 4h^2$.

Construct the scales

$$x = 15(C/\gamma H) \qquad y = 5 \tan \phi$$

$$x_1 = \frac{30}{3\cos^2 i + 1}\cos^2 i \qquad y_1 = \frac{15}{3\cos^2 i + 1}\cos^2 i \tan i$$

Notice that the rectangular equation of the (x_1, y_1) curve is

$$\frac{(x_1 - \frac{15}{4})^2}{(\frac{15}{4})^2} + \frac{y_1^2}{(\frac{15}{4})^2} = 1$$

which is a circle with center at $(\frac{15}{4}, 0)$ and radius equal to $\frac{15}{4}$. The chart in Fig. 29-82 shows that for any given value of ϕ, there are two values of i which give the same stability number.

Example 2. Chordal height and length of chord

$$d^2 = 8rh - 4h^2$$

where r = radius of the circle
d = length of the chord
h = chordal height

On the chart in Fig. 29-83, m_1 0.2, m_1 = 1, and k = 11.2 in.

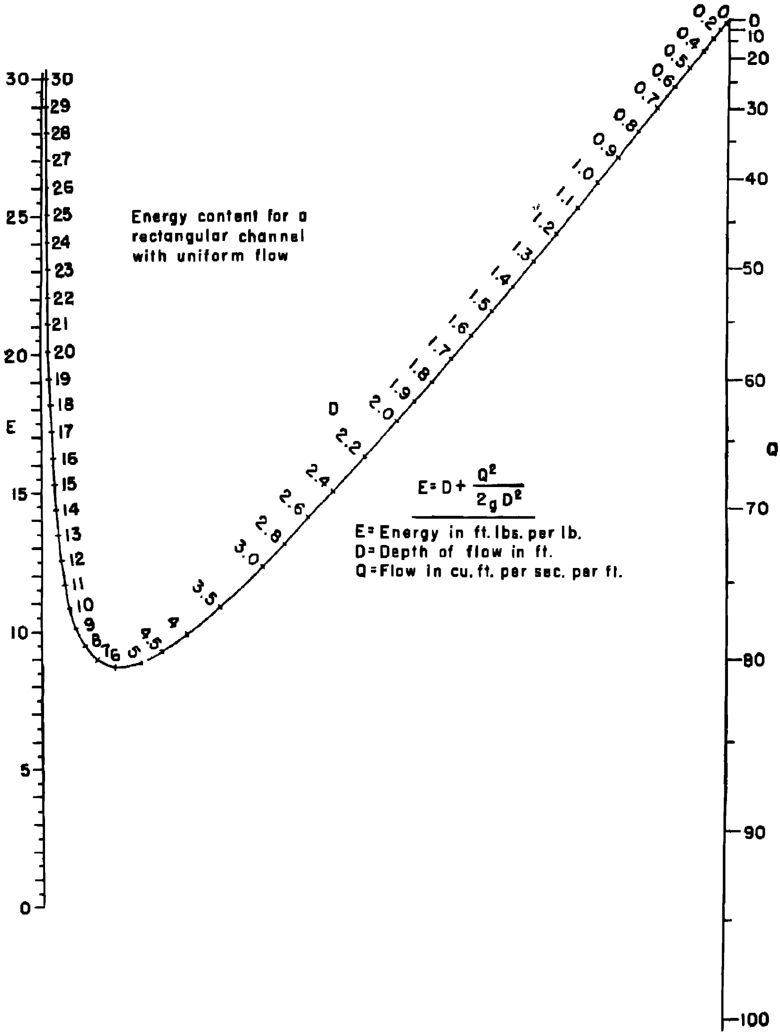

FIG 29-83a.

EXAMPLE 3. Energy content for a rectangular channel with uniform flow

$$E = D + (Q^2/2gD^2)$$

where E = energy, ft-lb per lb
D = depth of flow, ft
Q = flow, cu ft/(sec)/(ft) (Fig. 29-83a)

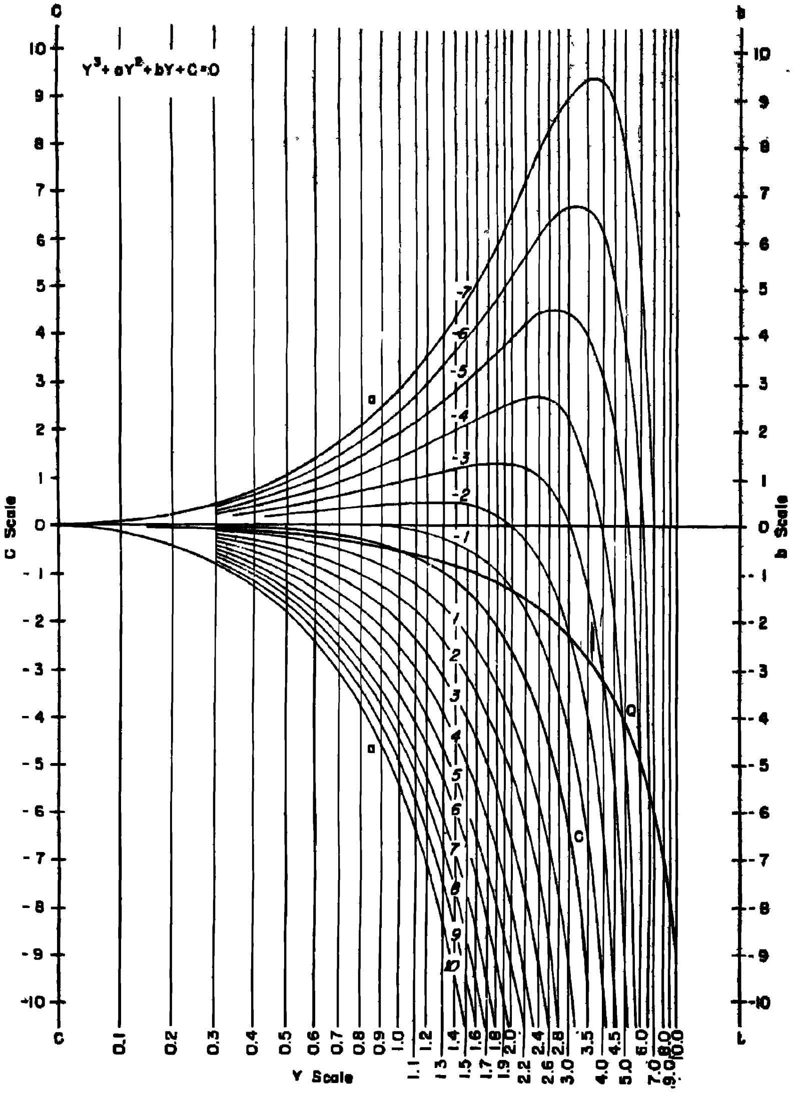

FIG. 29-84.

Example 4. Cubic equation. Figure 29-84 is a chart for the real value solutions of the cubic equation $y^3 + ay^2 + by + c = 0$. For each value of a, a single curve of (x_1, y_1) is produced. If a is zero, only the curve marked C is necessary to solve the equation $y^3 + by + c = 0$. If $c = 0$, then $y^2 + ay + b = 0$, use the curve marked Q.

Example 5. Francis formula for contracted weir (Fig. 29-85).

$$Q = 3.33(B - 0.2H)H^{3/2}$$

11. $$\frac{f_1(u)}{f_2(v)} = \frac{f_3(w)}{f_4(t)} \quad \text{or} \quad f_1(u)f_4(t) = f_2(v)f_3(w)$$

Scales are laid off on two parallel axes OX and $O'Y$, drawn in opposite directions and at any distance K apart (Fig. 29-86a). Lay off the scales $m_1f_1(u)$ and $m_3f_3(w)$ on the OX axis and $m_2f_2(v)$ and $m_4f_4(t)$ on the $O'Y$ axis. The moduli are related by the equation

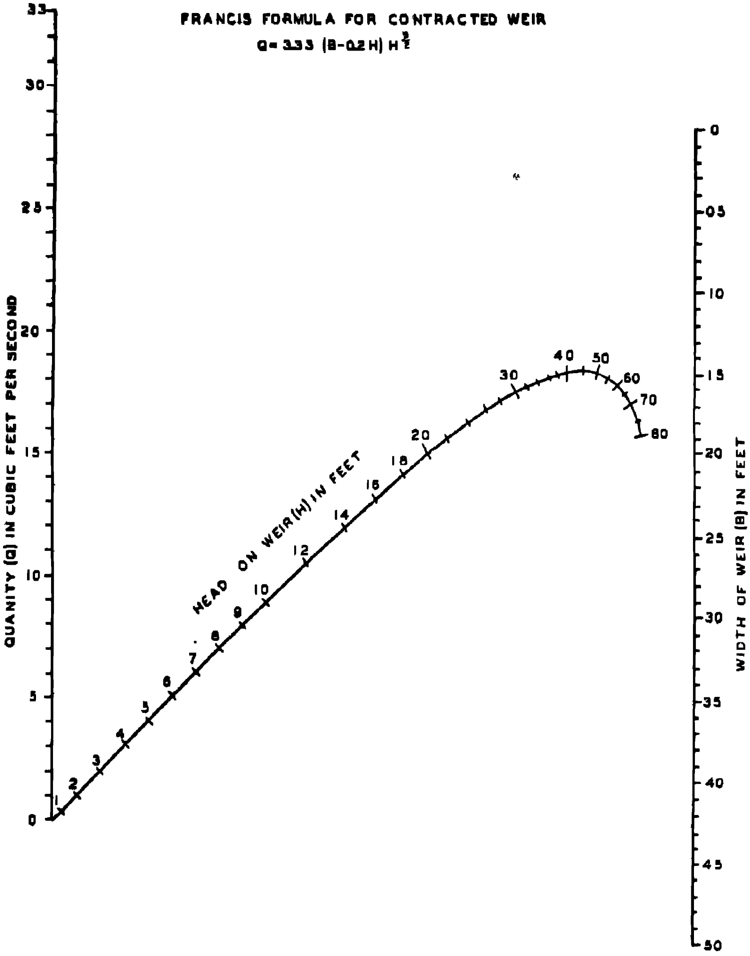

Fig. 29-85.

$$m_1/m_2 = m_3/m_4$$

Two index lines intersecting in a point on OO' will give values of u, v, w, and t satisfying the equation. A chart for the equation $u_1/v_1 = u_2/v_2$ is shown in Fig. 29-87. Boyle's law is shown in Fig. 29-87a. Draft correction for salt- and fresh-water-going vessels is shown in Fig. 29-87b.

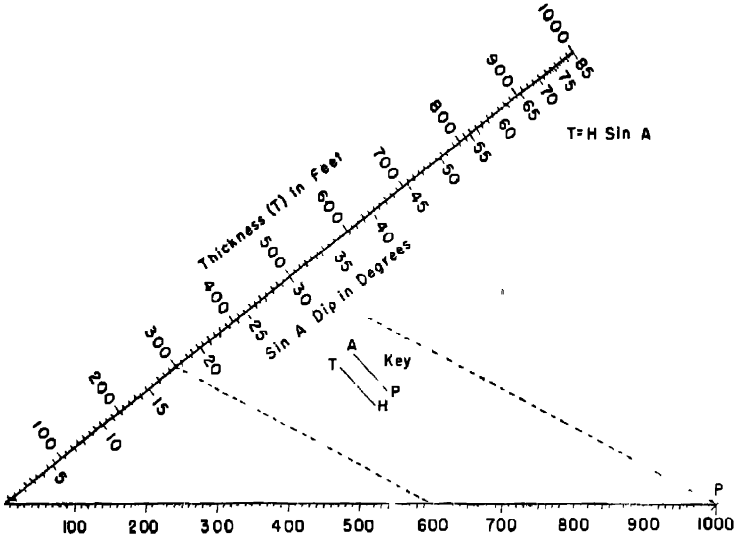

FIG 29-87c.

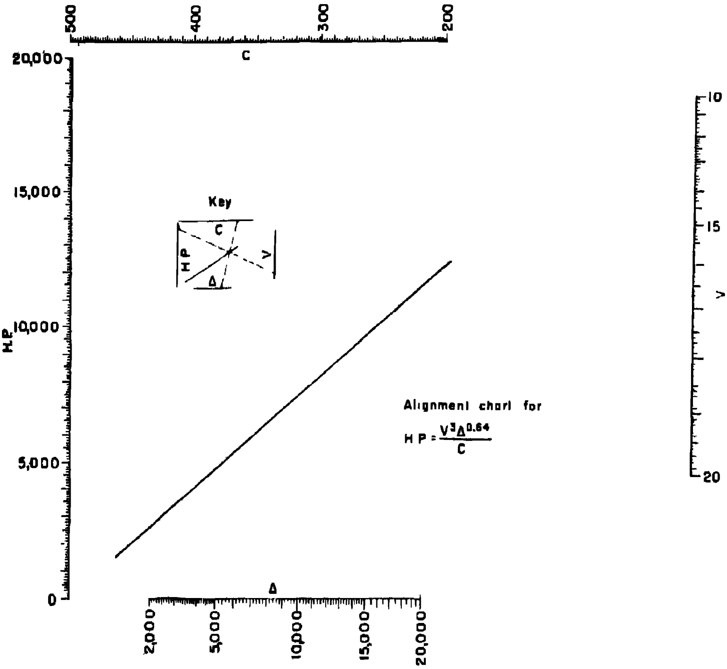

FIG. 29-87d.

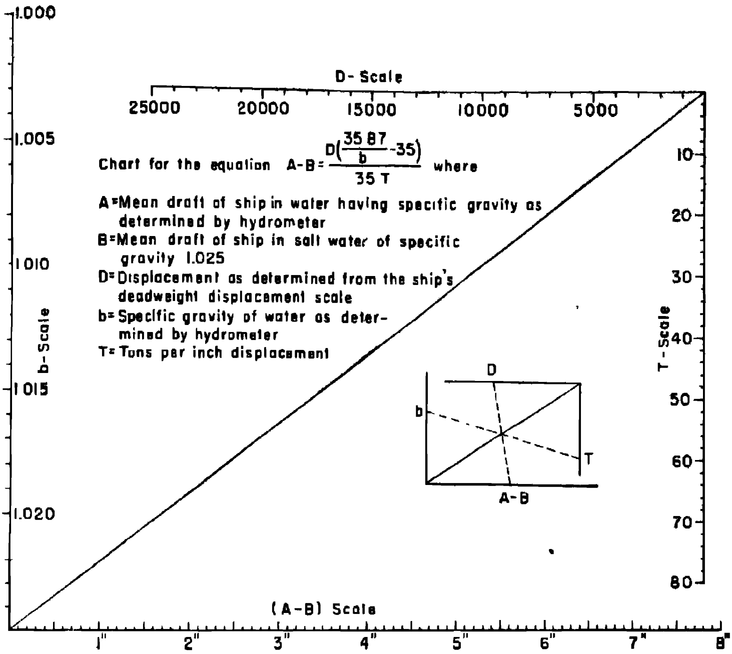

Fig. 29-87e.

It should be noticed that the two equal angles on whose sides scales are constructed may be placed in various positions as indicated in Figs. 29-86b, 29-86c.

The charts for $T = H \sin A$ (Fig. 29-87c), Hp $= V^3\Delta^{0.64}/C$ (Fig. 29-87d),

$$A - B = D\{[(35.87/b) - 35]/35T\}$$

(Fig. 29-87e), and the equation $1/u\sqrt{v} = \sqrt[3]{w}/t$ (Fig. 29-87f) illustrate this type.

11a. $$f_1(u) = f_3(w) \cdot f_2(v)$$

If $f_4(t) = C$ (constant) in type 11, then $f_1(u) = [f_3(w) \cdot f_2(v)]/C$. Consequently the t scale in type 11 is replaced by a single fixed point. In this case, however, it is convenient to project through the fixed point each of the points on the w scale onto the line OO'.

The form of the completed chart is shown in Fig. 29-88c.

11b. $$f_1(u) = Cf_2(v)$$

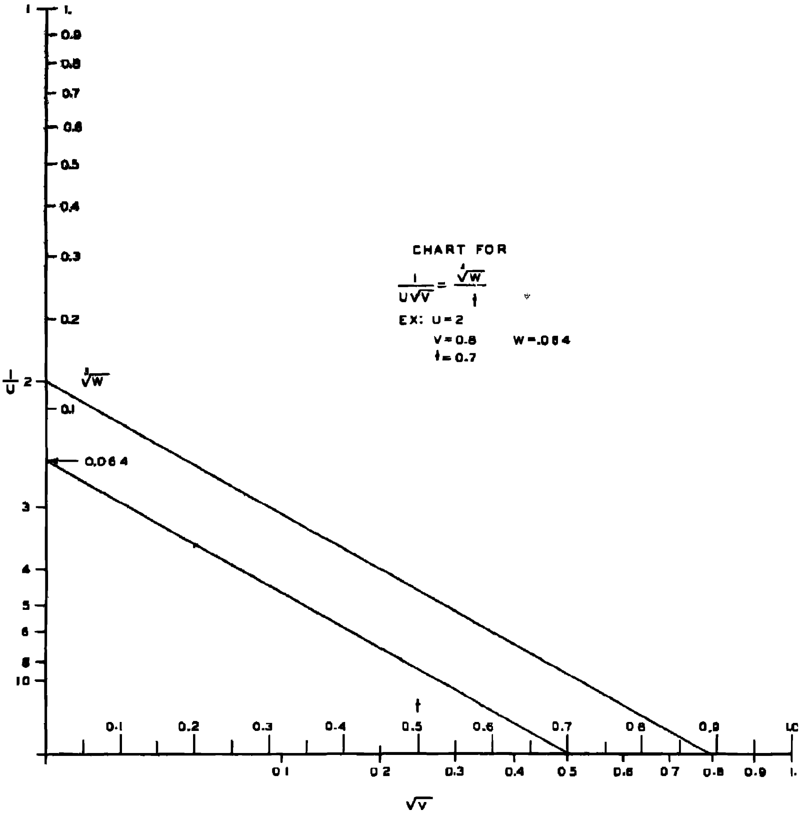

FIG. 29-87*f*.

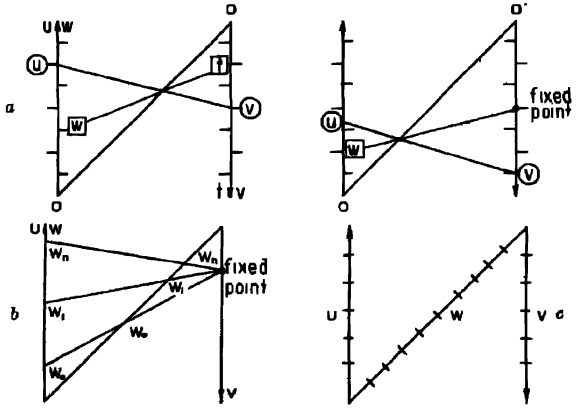

FIG. 29-88. $f_1(u) = f_3(w) \cdot f_2(v)$.

FIG. 29-90.

If $f_3(w) = C$ (constant) and $f_4(t) = 1$, type 11 reduces to the form $f_1(u) = Cf_2(v)$. By the method used in 11, the chart would appear to be as in Fig. 29-91. An index line joining the two fixed points would determine a fixed point P on the intersecting line OO'.

Consequently, to chart an equation of the form $f_1(u) = Cf_2(v)$, draw the scales for $f_1(u)$ and $f_2(v)$, assign a value to v, and find the corresponding value of u from the equation. Draw the index line between the values of u and v, and where the index line cuts the line OO' at P, a fixed turning point is established.

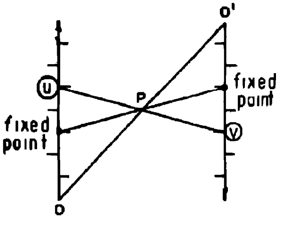

Fig. 29-91. $f_1(u) = Cf_2(v)$.

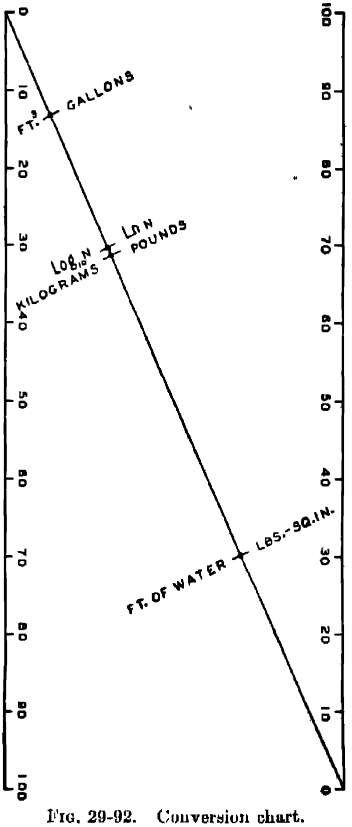

Fig. 29-92. Conversion chart.

This is a convenient type of chart to use for conversion formulas. It is evident that an infinite number of conversion formulas can be solved on one chart. Each fixed point is a key to a definite formula.

Figure 29-92 illustrates this type of chart.

11c. $$f_1(u) \cdot f_2(v) \cdots = f_i(r) \cdot f_j(s) \cdots$$

This is obviously an extension of type 11. For example, if

$$f_1(u) \cdot f_2(v) \cdot f_3(w) = f_4(t) \cdot f_5(s)$$

we can write

$$f_1(u) \cdot f_2(v) \cdot f_3(w) \cdot Q = f_4(t) \cdot f_5(s) \cdot Q \cdot 1$$

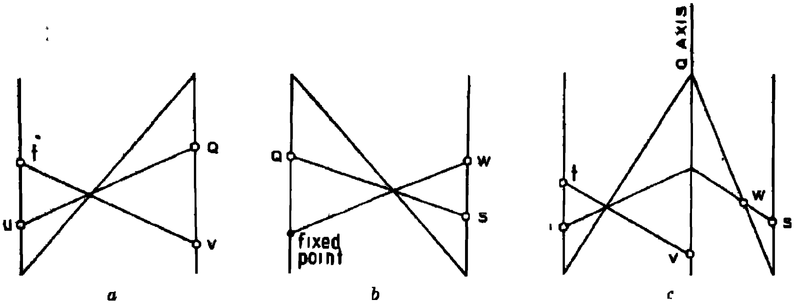

FIG. 29-93. $f_1(u) \cdot f_2(v) \cdots = f_i(r) \cdot f_j(s) \cdots$.

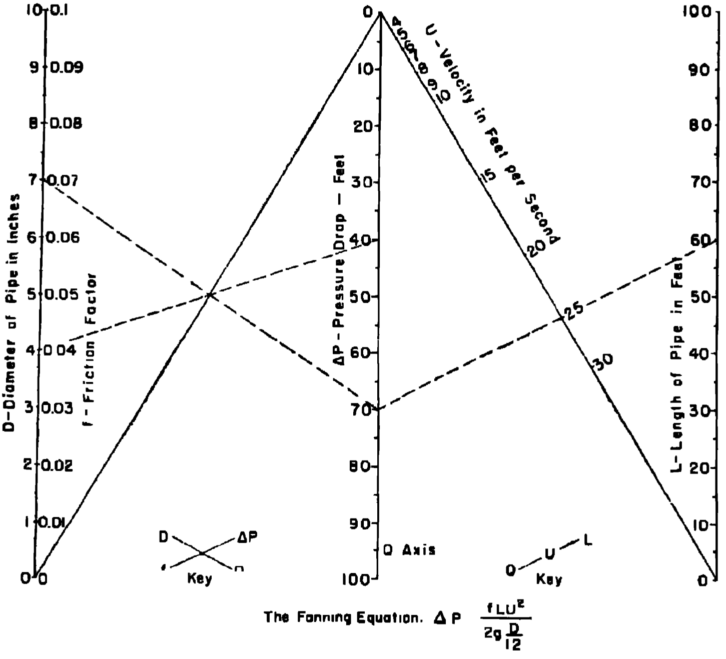

FIG. 29-94a.

where Q is an auxiliary variable. The latter equation may be written in the form

$$\frac{f_1(u)}{Q} = \frac{f_4(t)}{f_2(v)} \quad \text{and} \quad \frac{Q}{f_6(s)} = \frac{1}{f_3(w)}$$

Figures 29-94a, 29-94b, and 29-94c are charts of this type.

11d. $f_1(u) = Cf_2(v)$ (C is constant)

Taking logarithms of both members the equation becomes

$$\log f_2(v) = \log f_1(u) - \log C$$

or

$$\log f_1(u) - \log f_2(v) = \log C$$

FIG. 29-94b.

By the first equation we have two parallel scales, while the third scale is reduced to a point.

A conversion chart is shown by Fig. 29-96.

Generalization and Combinations. Sometimes an equation may be in such a form as not to adapt itself immediately to one of the previously suggested cases. When this situation arises, it may be possible to introduce one or more auxiliary variables

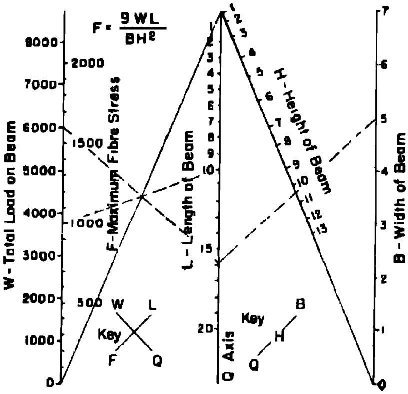

FIG. 29-94c.

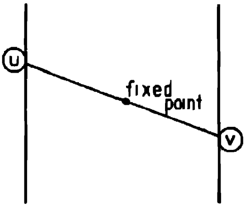

FIG. 29-95. $f_1(u) = Cf_2(v)$.

and split the original equation into two or more parts, applying one or more of the proposed forms to each of the various parts. In other cases, by holding one variable constant, a single scale is produced. Then for the complete range of that variable, a series of scales results. This situation gives rise to a so-called network of scales. Nothing new is involved since it is an obvious extension of the previous forms discussed. It is evident that a six-variable relationship might be represented by three sets of networks, which is analogous to three scales for a three-variable relationship. The possible forms suggested are illustrated by the following typical equations:

K = 7580 for flow inside rough pipes

K = 8850 for flow inside smooth pipes

Other symbols same as listed on charts

Fig 29-108

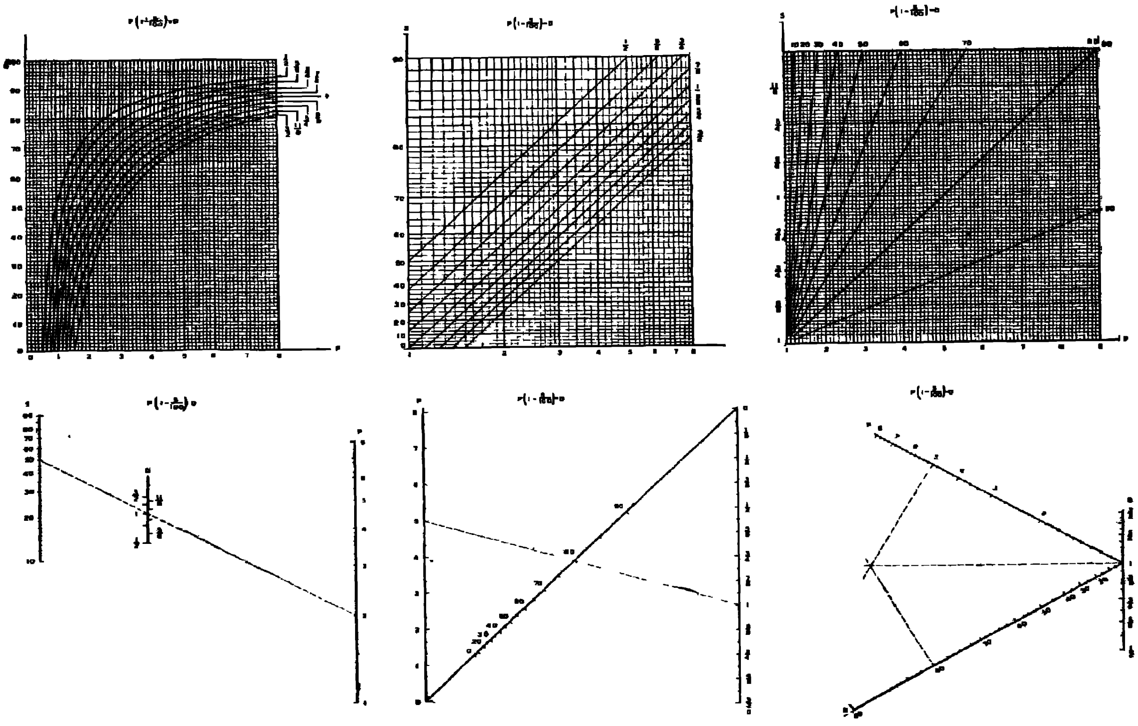

FIG. 29-109.

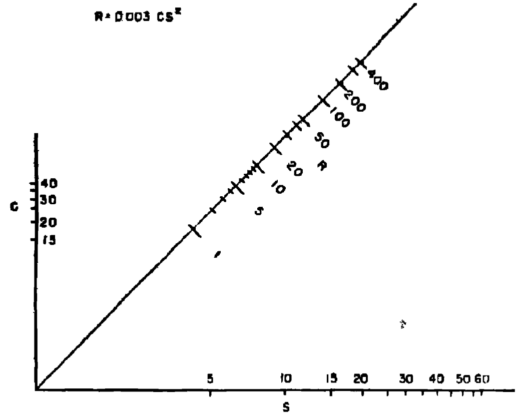

Fig. 29-110a.

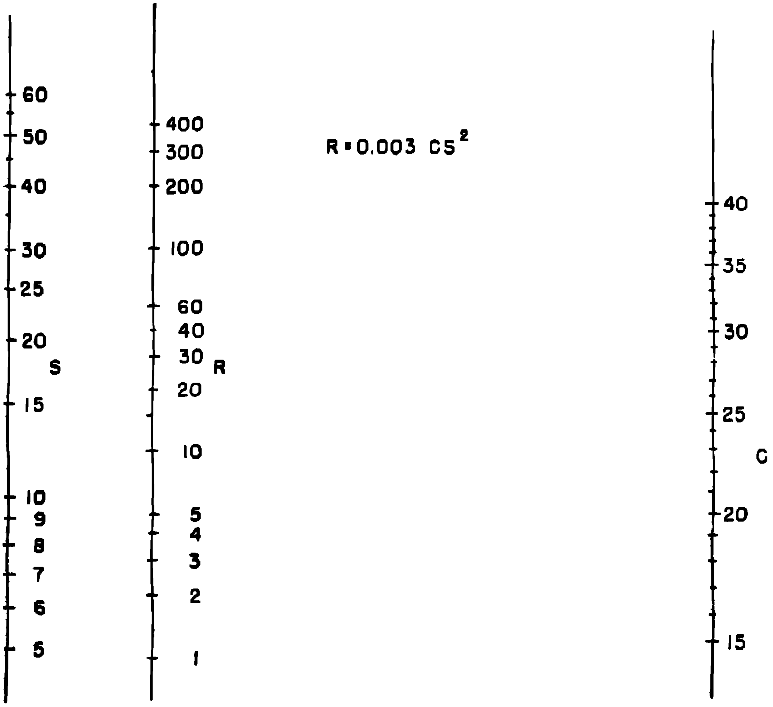

Fig 29-110b.

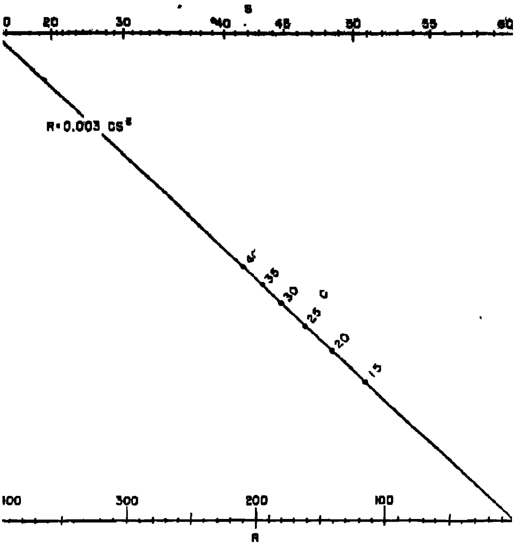

FIG. 29-110c.

DETERMINANT AS THE BASIS OF A NOMOGRAM

The condition that any three points (x_1, y_1), (x_2, y_2), and (x_3, y_3) lie on a straight line is that the determinant

$$\begin{vmatrix} x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \end{vmatrix} = 0$$

In the case of an equation containing three variables u, v, and w, it is possible to express the equation in the form of the above determinant. It is also possible to construct a nomogram.

For example, the determinant

$$\begin{vmatrix} f_1(u) & g_1(u) & 1 \\ f_2(v) & g_2(v) & 1 \\ f_3(w) & g_3(w) & 1 \end{vmatrix} = 0$$

states that the three axes carry the scales

$$x_1 = f_1(u) \qquad y_1 = g_1(u) \tag{1}$$
$$x_2 = f_2(v) \qquad y_2 = g_2(v) \tag{2}$$
$$x_3 = f_3(w) \qquad y_3 = g_3(w) \tag{3}$$

and that values of u, v, and w satisfying the determinant equation lie on a straight line.

Here Eq. (1) is the parametric representation of a curve on which are marked the values of u at each point having the coordinates (x_1, y_1). Similarly, Eqs. (2) and (3) are the curves on which are marked the values of v and w, respectively.

The determinant

$$\begin{matrix} 2u & 1| \\ v-1 & 0 \end{matrix}$$

is one way of writing the equation

$$w(1 + 2u - v) + w^2(v - u) - u(v + 1) = 0$$

The equation of the curve on which the u scale is marked is $x = u$, $y = 2u$, in parametric form, or the straight line $y = 2x$ in rectangular coordinates.

The equation of the curve on which the v scale is marked is $x = v$, $y = v - 1$, in parametric form, or the straight line $y = x - 1$ in rectangular coordinates.

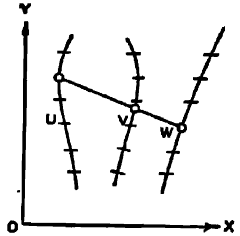

FIG. 29-111.

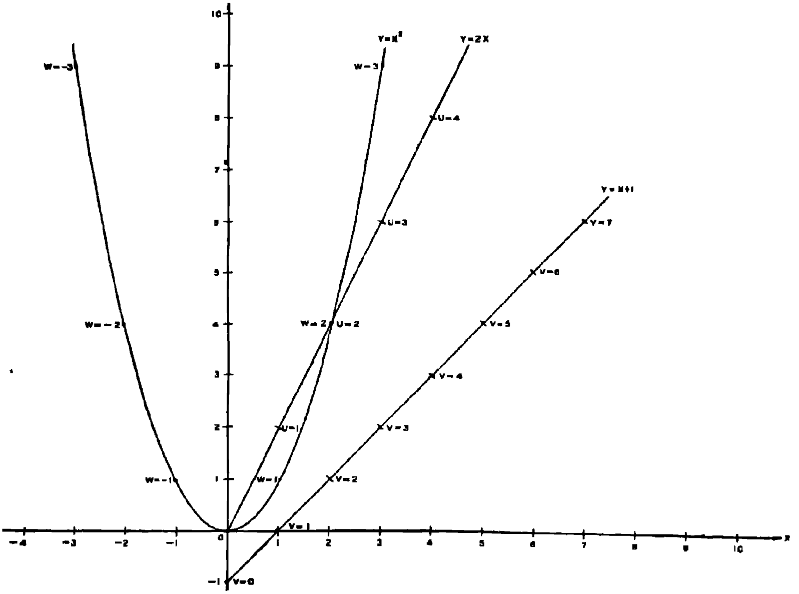

FIG. 29-112. $w(1 + 2u - v) + w^2(v - u) - u(v + 1) = 0.$

The equation of the curve on which the w scale is marked is $x = w$, $y = w^2$, in parametric form, or the parabola $y = x^2$ in rectangular coordinates. The appearance of the chart is shown in Fig. 29-112.

The general method of deriving the determinant form of an equation consists in forming three simultaneous equations of the form $Ax + By + C = 0$, from which the determinant

$$\begin{vmatrix} A_1 & B_1 & C_1 \\ A_2 & B_2 & C_2 \\ A_3 & B_3 & C_3 \end{vmatrix} = 0$$

may be derived directly by writing the coefficients of the equation in the order shown. It is then necessary to transform this determinant into the basic form where the elements occurring in one column are each equal to unity. This can be accomplished by using the well-known properties of determinants.

1. Rows may be changed into columns and columns into rows.
2. Any two rows or columns may be interchanged.
3. All the elements of a row or column may be multiplied or divided by the same quantity.
4. To the element of any row or column may be added the same multiples of the corresponding element of any one or more other rows or columns.

For example, consider the equation,

$$s = v_0t - 16t^2$$

Rewrite the equation in the form,

$$w = vu - 16u^2 \qquad \text{or} \qquad 16u^2 - uv + w = 0$$

Let $x = v$ and $y = w$; then the following three equations are obtained.

$$16u^2 - xu + y = 0$$
$$x - v = 0$$

and

$$y - w = 0$$

Each of these equations is of the form

$$Ax + By + C = 0$$

and may be written as

$$x + 0y - v = 0$$
$$0x + y - w = 0$$

and

$$-ux + y + 16u^2 = 0$$

Since the equations are simultaneously true, the following determinant

$$\begin{vmatrix} 1 & 0 & -v \\ 0 & 1 & -w \\ -u & 1 & 16u^2 \end{vmatrix} = 0$$

A new determinant with a column of ones must be found, using the properties of determinants. This may be done as follows:

1. Adding the elements of the first and second columns, we obtain

$$\begin{vmatrix} 1 & 0 & -v \\ 1 & 1 & -w \\ 1-u & 1 & 16u^2 \end{vmatrix} = 0$$

2. Dividing the third row by $1 - u$ and interchanging the first and third columns, we obtain

$$\begin{array}{cc} -v & 0 \\ -w & 1 \\ 16u^2 & 1 \\ u & \end{array} = 0$$

which is a basic form.

3. For convenience interchange the first and second columns. Then

$$\begin{array}{ccc} 0 & -v & 1 \\ 1 & -w & 1 \\ \dfrac{1}{1-u} & \dfrac{16u^2}{1-u} & 1 \end{array}$$

The equations of the scales are

$$\begin{array}{ll} x & -v \\ x & -w \\ x = \quad 1-u & \dfrac{16u^2}{1-u} \end{array}$$

Scale factors may be introduced in a variety of ways. One way is to multiply the first and second columns by d and m, respectively. The form of the determinant is

$$\begin{array}{ccc} 0 & -mv & 1 \\ d & -mw & 1 \\ d & 16mu^2 & , \\ 1-u & 1 & \cdot\, u \end{array}$$

where m and d are determined by the range of the variables and the desired size of the chart.

Another way is to introduce scale factors at the beginning.

Let $x = m_1v$ and $y = m_2w$ in the equation $16u^2 - uv + w = 0$. Then the following three equations are obtained:

$$16u^2 - (x/m_1)u + (y/m_2) = 0$$
$$x - m_1v = 0$$

and

$$y - m_2w = 0$$

which may be written

$$-(u/m_1)x + (1/m_2)y + 16u^2 = 0$$
$$x + 0y - m_1v = 0$$
$$0x + y - m_2w = 0$$

Therefore

$$\begin{vmatrix} -\dfrac{u}{m_1} & \dfrac{1}{m_2} & 16u^2 \\ 1 & 0 & -m_1v \\ 0 & 1 & -m_2w \end{vmatrix} = 0$$

By properties of determinants, the resulting determinant is obtained:

$$\begin{vmatrix} 0 & -m_1v & 1 \\ 1 & -m_2w & 1 \\ \dfrac{m_1}{-m_2u + m_1} & \dfrac{16m_1m_2u^2}{-m_2u + m_1} & 1 \end{vmatrix} = 0$$

In order to control distances between scales, multiply the elements of the first column by d. Thus, the constructional form of the determinant is

$$\begin{vmatrix} 0 & -m_1v & 1 \\ d & -m_2w & 1 \\ \dfrac{m_1d}{-m_2u + m_1} & \dfrac{16m_1m_2u^2}{-m_2u + m_1} & 1 \end{vmatrix} = 0$$

A check on the work at any time can be made by expanding the determinant at that stage of the work, and the resulting equation will be the original one. Thus a check on the final form arrived at is

$$\frac{-m_1^2dv}{-m_2u + m_1} + \frac{16m_1m_2du^2}{-m_2u + m_1} + \frac{m_1m_2dw}{-m_2u + m_1} + m_1dv = 0$$

or

$$16u^2 - uv + w = 0$$

Consider a second equation of the form

$$\frac{1}{f_2(v)} + \frac{1}{f_4(t)} = \frac{1}{f_1(u)}$$

or

$$f_1(u) \cdot f_4(t) + f_1(u) \cdot f_2(v) = f_2(v) \cdot f_4(t)$$

previously discussed

The corresponding determinant form is

$$\begin{vmatrix} f_2(v) & 0 & 1 \\ f_1(u) & f_1(u) & 1 \\ 0 & f_4(t) & 1 \end{vmatrix} = 0$$

The constructional determinant can be conveniently written

$$\begin{vmatrix} m_1f_2(v) & 0 & 1 \\ m_1f_1(u) & m_2f_1(u) & 1 \\ 0 & m_2f_4(t) & 1 \end{vmatrix} = 0$$

The scales are

$$x = m_1f_2(v) \qquad y = 0$$
$$x = m_1f_1(u) \qquad y = m_2f_1(u)$$
and
$$x = 0 \qquad y = m_2f_4(t)$$

It should be noted that, if $m_1 = m_2$, the axis carrying the u scale bisects the angle between the axes.

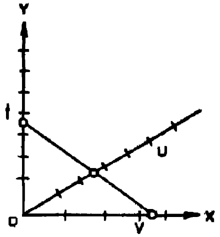

Fig. 29-113. $\frac{1}{f_2(v)} + \frac{1}{f_4(t)} = \frac{1}{f_1(u)}$.

Common Types. The basic determinant together with its constructional determinant and form of chart is shown for common types of equations occurring in practice:

1. $f_1(u) + f_2(v) = f_3(w)$

$$\begin{vmatrix} -1 & f_1(u) & 1 \\ 1 & f_2(v) & 1 \\ 0 & \tfrac{1}{2}f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} -d_1 & m_1f_1(u) & 1 \\ d_2 & m_2f_2(v) & 1 \\ 0 & \dfrac{m_1m_2}{m_1 + m_2}f_3(w) & 1 \end{vmatrix} = 0$$

where $m_1/m_2 = d_1/d_2$.

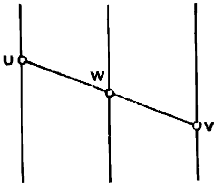

Fig. 29-114.

2. $f_1(u) + f_2(v) \cdot f_3(w) - kf_2(v) - f_1(u) \cdot f_2(v) = 0$

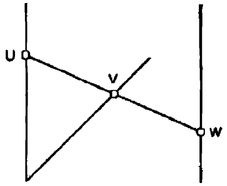

Fig. 29-115.

$$\begin{vmatrix} 0 & f_1(u) & 1 \\ f_2(v) & kf_2(v) & 1 \\ 1 & f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} 0 & m_1f_1(u) & 1 \\ \dfrac{dm_1f_2(v)}{(m_1 - m_2)f_2(v) + m_2} & \dfrac{m_1m_2kf_2(v)}{(m_1 - m_2)f_2(v) + m_2} & 1 \\ d & m_2f_3(w) & 1 \end{vmatrix} = 0$$

$$f_3(w) = \frac{f_1(u)}{f_1(u) + f_2(v)}$$

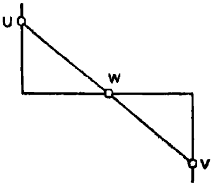

Fig. 29-116.

$$\begin{vmatrix} 0 & f_1(u) & 1 \\ f_3(w) & 0 & 1 \\ 1 & -f_2(v) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} 0 & m_1f_1(u) & 1 \\ \dfrac{dm_1f_3(w)}{(m_1 - m_2)f_3(w) + m_2} & 0 & 1 \\ d & -m_2f_2(v) & 1 \end{vmatrix} = 0$$

4. $$f_3(w) = \frac{f_1(u)}{f_2(v)}$$

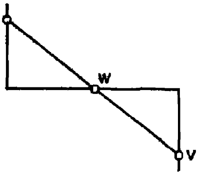

FIG. 29-117.

$$\begin{vmatrix} 0 & f_1(u) & 1 \\ \dfrac{f_3(w)}{1 + f_3(w)} & 0 & 1 \\ 1 & -f_2(v) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} 0 & m_1 f_1(u) & 1 \\ \dfrac{dm_1 f_3(w)}{m_1 f_3(w) + m_2} & 0 & 1 \\ d & -m_2 f_2(v) & 1 \end{vmatrix} = 0$$

5. $$f_3(w) = \frac{f_1(u) \cdot f_2(v)}{f_1(u) + f_2(v)}$$

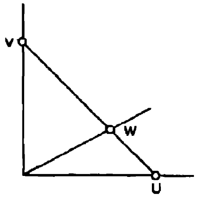

FIG. 29-118.

$$\begin{vmatrix} f_1(u) & 0 & 1 \\ 0 & f_2(v) & 1 \\ f_3(w) & f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} df_1(u) & 0 & 1 \\ 0 & mf_2(v) & 1 \\ df_3(w) & mf_3(w) & 1 \end{vmatrix} = 0$$

6. $$f_1(u) - f_2(v) + \phi(v)[f_3(w) - f_1(u)] = 0$$

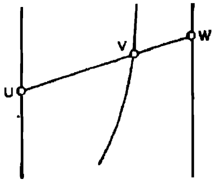

FIG. 29-119.

$$\begin{vmatrix} 0 & f_1(u) & 1 \\ \phi(v) & f_2(v) & 1 \\ 1 & f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} 0 & m_1 f_1(u) & 1 \\ \dfrac{km_1\phi(v)}{(m_1 - m_2)\phi(v) + m_2} & \dfrac{m_1 m_2 f_2(v)}{(m_1 - m_2)\phi(v) + m_2} & 1 \\ K & m_2 f_3(w) & 1 \end{vmatrix} = 0$$

7. $$f_1(u) \cdot f_2(v) + \phi(v) \cdot f_3(w) - f_3(w) \cdot f_1(u) = 0$$

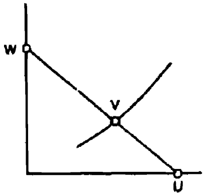

FIG. 29-120.

$$\begin{vmatrix} f_1(u) & 0 & 1 \\ \phi(v) & f_2(v) & 1 \\ 0 & f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} df_1(u) & 0 & 1 \\ d\phi(v) & mf_2(v) & 1 \\ 0 & mf_3(w) & 1 \end{vmatrix} = 0$$

8. $$f_3(w) = \frac{f_1(u)\cdot\phi(v) - \phi(u)\cdot f_2(v)}{\phi(v) - \phi(u)}$$

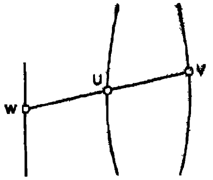

FIG. 29-121.

$$\begin{vmatrix} \phi(u) & f_1(u) & 1 \\ \phi(v) & f_2(v) & 1 \\ 0 & f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} k\phi(u) & mf_1(u) & 1 \\ k\phi(v) & mf_2(v) & 1 \\ 0 & mf_3(w) & 1 \end{vmatrix} = 0$$

9. $$\phi_1(u)[f_2(v) - f_3(w)] + \phi_2(v)[f_3(w) - f_1(u)] + \phi_3(w)[f_1(u) - f_2(v)] = 0$$

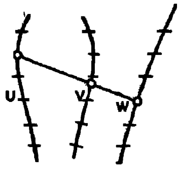

FIG. 29-122.

$$\begin{vmatrix} \phi_1(u) & f_1(u) & 1 \\ \phi_2(v) & f_2(v) & 1 \\ \phi_3(w) & f_3(w) & 1 \end{vmatrix} = 0 \qquad \begin{vmatrix} m_1\phi_1(u) & m_2f_1(u) & 1 \\ m_1\phi_2(v) & m_2f_2(v) & 1 \\ m_1\phi_3(w) & m_2f_3(w) & 1 \end{vmatrix} = 0$$

Specific Equations Expressed in Determinant Form. As illustrations of equations expressed in the form of determinants are the following:

1. Flow of steam through pipes:

$$W = 15\pi d^2VD$$

$$\begin{vmatrix} \dfrac{15\pi d^2}{W} & 1 & 1 \\ 0 & \dfrac{V}{1+V} & 1 \\ -\dfrac{1}{D} & 0 & 1 \end{vmatrix} = 0 \quad \text{or} \quad \begin{vmatrix} \dfrac{15\pi d^2}{W} & 1 & 1 \\ 0 & \dfrac{D}{1+D} & 1 \\ -\dfrac{1}{V} & 0 & 1 \end{vmatrix} = 0$$

2. Boiler horsepower:

$$\text{Boiler hp} = 3.33(A - 0.6\sqrt{A})\sqrt{H}$$

$$\begin{vmatrix} \dfrac{10A}{3(1+2\sqrt{A})} & \dfrac{2\sqrt{A}}{1+2\sqrt{A}} & 1 \\ \dfrac{B}{\sqrt{H}} & 0 & 1 \\ 1 & 1 & 1 \end{vmatrix} = 0$$

3. Shear strength of rivets:

$$\gamma_s = \frac{\pi}{4}d^2f_s$$

$$\begin{vmatrix} \dfrac{\pi d^2}{4} & -1 & 1 \\ 0 & \dfrac{f_s}{1-f_s} & 1 \\ \gamma_s & 0 & 1 \end{vmatrix} = 0$$

4. Radius of gyration of circular cylinder:

$$K \qquad \sqrt{3R^2 + h^2}$$

$$--$$

$$\begin{vmatrix} 3R^2 & 0 & 1 \\ h^2 & 1 & 1 \\ 6K^2 & 1/2 & 1 \end{vmatrix} = 0$$

5. Capacitance of two parallel cylinders:

$$C = \frac{10^{-5}K}{36 \ln (d/\gamma)}$$

$$\begin{vmatrix} 36(10)^5C & 1 & 1 \\ 0 & \dfrac{\ln d}{1 + \ln d} & 1 \\ \dfrac{1}{1 + \ln \gamma} & \dfrac{\ln \gamma}{1 + \ln \gamma} & 1 \end{vmatrix} = 0$$

6. Blast-pressure furnace:

$$P^2 - 14.7^2 = 0.0007(w^2H/D^4)$$

$$\begin{vmatrix} \dfrac{0.0007w^2}{0.0007w^2 - 1} & 0 & 1 \\ 0 & D^4(P^2 - 14.7^2) & 1 \\ 1 & -H & 1 \end{vmatrix} = 0$$

7. Brake horsepower:

$$\text{Bhp} = d^2n/2.5$$

$$\begin{vmatrix} 2.5 \text{ bhp} & 1 & 1 \\ d^2 & 0 & 1 \\ 0 & \dfrac{1}{1 - m} & 1 \end{vmatrix} = 0$$

8. Francis weir formula:

$$Q = 3.33(B - 0.2H)H^{3/2}$$

$$\begin{vmatrix} \dfrac{H^{3/2}}{H^{3/2} + 5} & \dfrac{H^{5/2}}{H^{5/2} + 5} & 1 \\ \dfrac{1}{5B} & 1 & 1 \\ 0 & \dfrac{Q}{Q - 3.33} & 1 \end{vmatrix} = 0$$

9. Lens formula:

$$\frac{1}{f} = \frac{1}{u} + \frac{1}{V}$$

$$\begin{vmatrix} \dfrac{1}{u} & 1 & 1 \\ \dfrac{1}{V} & -1 & 1 \\ \dfrac{1}{2f} & 0 & 1 \end{vmatrix} = 0$$

10. Moment of inertia of a cylinder:

$$I = \frac{W}{12}(3R^2 + h^2)$$

$$\begin{vmatrix} \dfrac{W}{12} & 1 & 1 \\ 0 & \dfrac{R^2}{R^2 - 1} & 1 \\ \dfrac{I}{h^2 + 3} & \dfrac{h^2}{h^2 + 3} & 1 \end{vmatrix} = 0$$

11. Cubic equation:

$$w^3 + nw^2 + Pw + q = 0$$

$$\begin{vmatrix} \dfrac{w}{w+1} & -\dfrac{w^3+nw^2}{w+1} & 1 \\ 0 & q & 1 \\ 1 & P & 1 \end{vmatrix} = 0$$

Examples:

1. Chordal height and length of chord:

$$d^2 = 8rh - 4h^2$$

Expressed in determinant form, the equation is

$$\begin{vmatrix} 0 & \dfrac{d^2}{40} & 1 \\ 11\ 2 & -r & 1 \\ \dfrac{22\ 4h}{2h+10} & -\dfrac{h^2}{2h+10} & 1 \end{vmatrix} = 0$$

The chart is shown in Fig. 29-123.

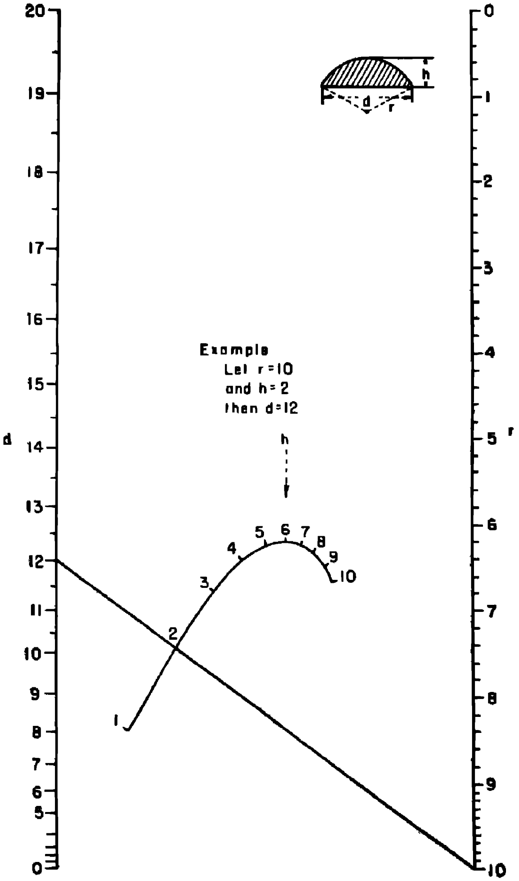

FIG. 29-123. $d^2 = 8rh - 4h^2$.

2.
$$A = \frac{4}{3} H^2 \sqrt{\frac{2R}{H} - 0.608}$$

The determinant form of the equation is

$$\begin{vmatrix} 0 & \dfrac{A^2}{180{,}000} & \\ 5 & -\dfrac{4R}{125} & 1 \\ \dfrac{5H^3}{H^3 + 180} & \dfrac{1.216H^4}{125(H^3 + 180)} & 1 \end{vmatrix} = 0$$

The completed chart is shown in Fig. 29-124.

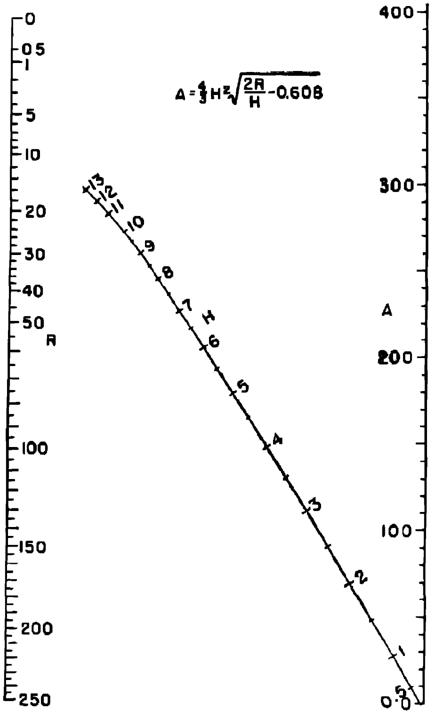

FIG 29-124.

3. Energy content for a rectangular channel with uniform flow:

$$E = D - (Q^2/2gD^2)$$

The determinant form of the equation is

$$\begin{vmatrix} 0 & \dfrac{12.2}{(100)^2} Q^2 & 1 \\ 9 & -\dfrac{E}{3} & 1 \\ \dfrac{9D^2}{D^2 + \dfrac{100^2}{73.2g}} & \dfrac{D^3}{3\left(D^2 + \dfrac{100^2}{73.2g}\right)} & 1 \end{vmatrix} = 0$$

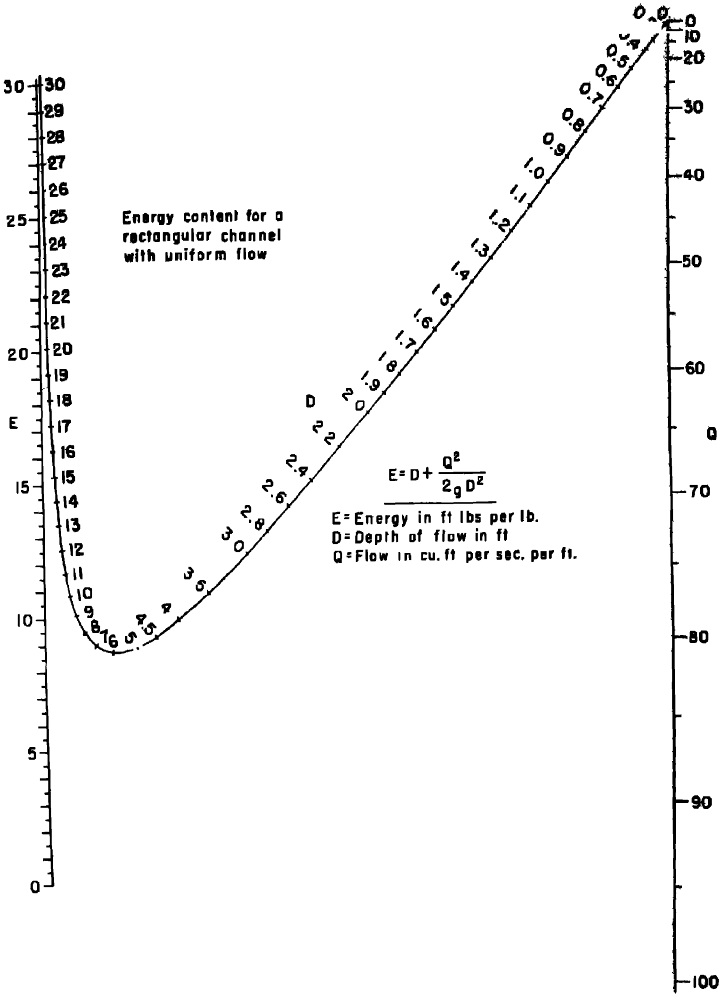

Fig. 29-125.

The completed chart is shown in Fig. 29-125.

4. Temperature in air-mixture otto cycle

$$Te^{BT} = C$$

Taking logarithms of both sides, we have

$$\log T - 0.4343BT = \log C$$

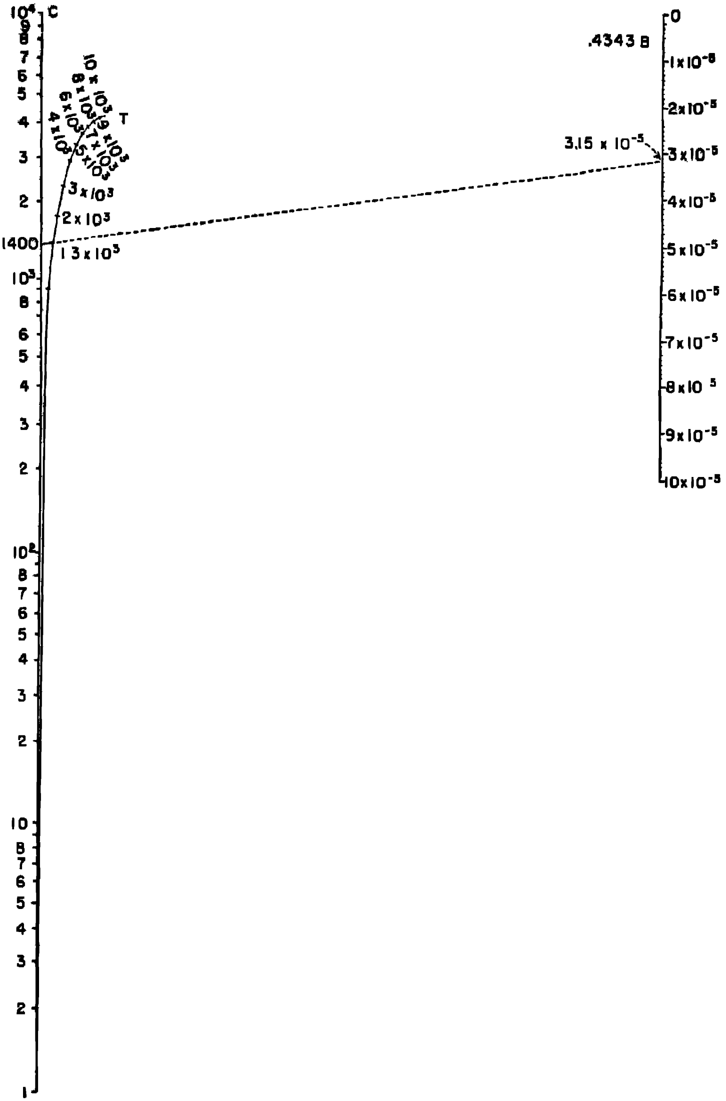

FIG. 29-126. $Te^{BT} = C$.

The determinant form and chart are shown in Fig. 29-126.

5. Mean temperature equation

$$T = \frac{T_1 - T_2}{\log_e T_1 - \log_e T_2} = \frac{T_1 - T_2}{\ln T_1 - \ln T_2}$$

Expressed in determinant form, the equation is

$$\begin{vmatrix} 0 & T & 1 \\ \dfrac{1}{\ln T_1} & \dfrac{T_1}{\ln T_1} & 1 \\ \dfrac{1}{\ln T_2} & \dfrac{T_2}{\ln T_2} & 1 \end{vmatrix} = 0$$

The chart is shown in Fig. 29-127.

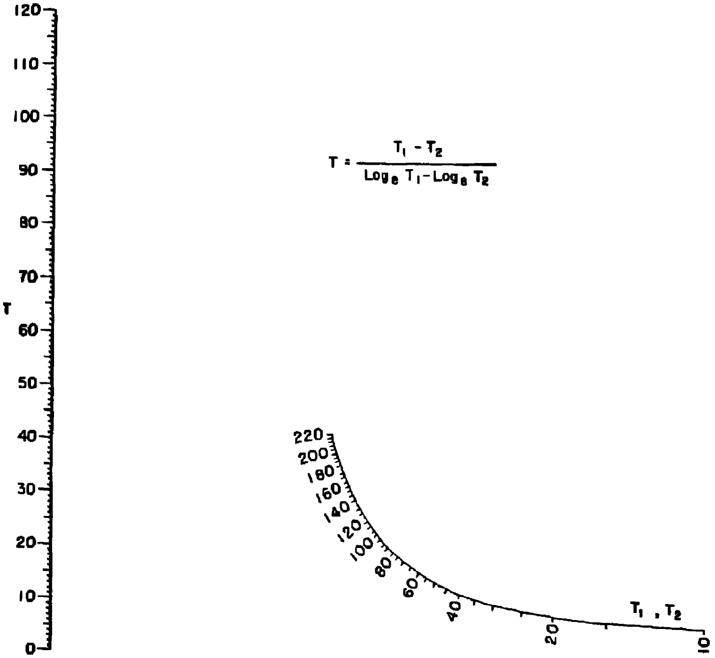

FIG. 29-127.

6. Equity debt equation

$$R = \frac{E - IP}{1 - P}$$

The determinant form of this equation is

$$\begin{vmatrix} 0 & \frac{3}{2}I & 1 \\ 12 & \frac{4}{13}R & 1 \\ \frac{468(1-P)}{39-31P} & \frac{12E}{39-31P} & 1 \end{vmatrix} = 0$$

The chart is shown in Fig. 29-128.

$$R = \frac{E - IP}{1 - P}$$

R = rate of return on equity
I = rate of interest on debt
P = proportion of debt to total capitalization
E = rate of earnings on total capitalization

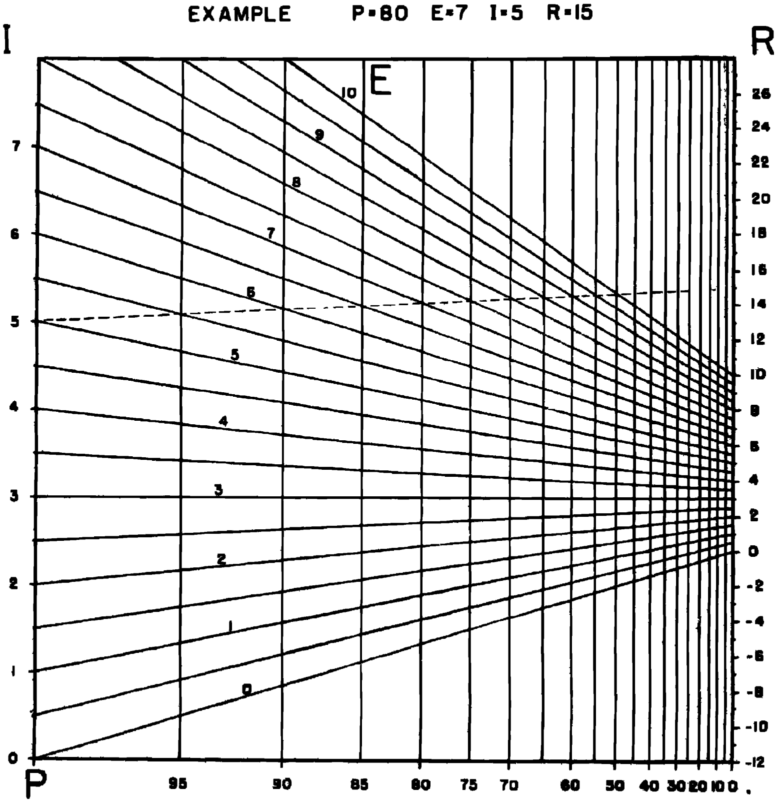

Fig. 29-128.

Circular Nomograms. The general form of the basic determinant for a circular nomogram is

$$\begin{vmatrix} \dfrac{1}{1 + [f_1(u)]^2} & \dfrac{f_1(u)}{1 + [f_1(u)]^2} & 1 \\ \dfrac{1}{1 + [f_2(v)]^2} & \dfrac{f_2(v)}{1 + [f_2(v)]^2} & 1 \\ \dfrac{1}{1 + f_3(w)} & 0 & 1 \end{vmatrix} = 0$$

from which it is seen that the u and v scales lie on circular axes having the same center and with radii equal to ½.

The constructional determinant form is

$$\begin{vmatrix} \dfrac{m_1}{1 + [f_1(u)]^2} & \dfrac{m_2 f_1(u)}{1 + [f_1(u)]^2} & 1 \\ \dfrac{m_1}{1 + [f_2(v)]^2} & \dfrac{m_2 f_2(v)}{1 + [f_2(v)]^2} & 1 \\ \dfrac{m_1}{1 + f_3(w)} & 0 & 1 \end{vmatrix} = 0$$

When $m_1 \neq m_2$, we will have arcs of ellipses instead of circles

In equations of the form $f_1(u) \cdot f_2(v) = f_3(w)$, the basic determinant is

$$\begin{vmatrix} \dfrac{1}{1 + [f_1(u)]^2} & \dfrac{f_1(u)}{1 + [f_1(u)]^2} & 1 \\ \dfrac{1}{1 + [f_2(v)]^2} & \dfrac{-f_2(v)}{1 + [f_2(v)]^2} & 1 \\ \dfrac{1}{1 + f_3(w)} & 0 & 1 \end{vmatrix} = 0$$

Consider the equation

$$AB \cos (\theta + \phi) + BU(\sin \phi - \cos \phi) + AU(\sin \theta - \cos \theta) = 0$$

The equation expressed in the form of a determinant is

$$\begin{vmatrix} A \sin \theta & A \cos \theta & 1 \\ B \cos \phi & B \sin \phi & 1 \\ U & U & 1 \end{vmatrix} = 0$$

The equations of the scales are

Circle of radius A:

$$x = A \sin \theta \qquad y = A \cos \theta$$

Circle of radius B:

$$x = B \cos \phi \qquad y = B \sin \phi$$

Straight line making an angle of 45 deg with the x-axis:

$$x = U \qquad y = U$$

Assume that $A = 5.12$ and $B = 2$.

The scale of θ is constructed on the outside, and the scale of ϕ is constructed on the inside of a circle, outside the chart, since the value of each angle is the same for each of the two basic circles along a radial line.

Consider the equation

$$AB \cos (\theta + \phi) + B(\sin \phi - \cos \phi) + A(\sin \theta - \cos \theta) = 0$$

where A, B, θ, and ϕ are variables.

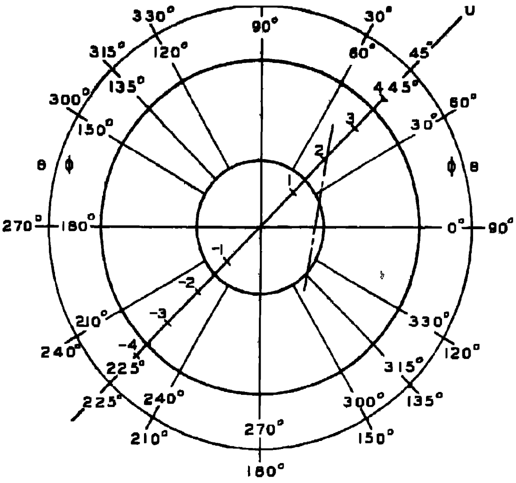

FIG. 29-129. $AB \cos(\theta + \phi) + BU(\sin\phi - \cos\phi) + AU(\sin\theta - \cos\theta) = 0$.

In determinant form, the equation is

$$\begin{vmatrix} A\sin\theta & A\cos\theta & 1 \\ B\cos\phi & B\sin\phi & 1 \\ 1 & 1 & 1 \end{vmatrix} = 0$$

The equations of the scales are

cles of radius A:

$$x = A\sin\theta \qquad y = A\cos\theta$$

cles of radius B:

$$x = B\cos\phi \qquad y = B\sin\phi$$

ed point:

$$x = 1 \qquad y = 1$$

The scales of θ and ϕ are constructed on a single circular axis as in previous stration.

Any line through the *fixed point* will cut the A and B circles in values of θ and ϕ ch satisfy the equation

$$AB\cos(\theta + \phi) + B(\sin\phi - \cos\phi) + A(\sin\theta - \cos\theta) \quad 0$$

From the construction of the chart, A and θ are paired together as are B and ϕ. For example, if $A = 5$, $\theta = 330$, and $B = 4$, find the value of ϕ.

Locate the point on the $A = 5$ circle where $\phi = 330$. (θ is graduated on the outside of the outer circle.) Lay a straightedge through this point and the fixed point. At each point where the straightedge cuts the $B = 4$ circle, draw radial lines from the common center, and read the value of ϕ on the inside of the outer circle. Two rotating dials, one at the common center and one at the fixed point, are convenient when this type of chart is used.

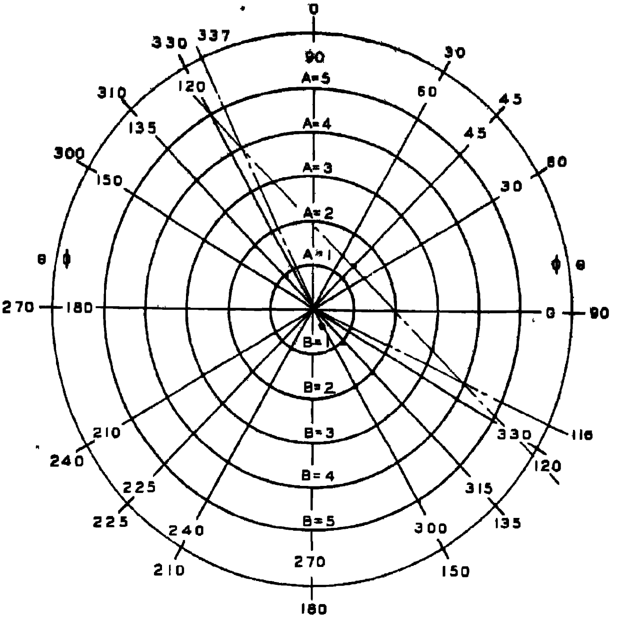

Fig. 29-130. $AB\cos(\theta+\phi) + B(\sin\phi - \cos\phi) + A(\sin\theta - \cos\theta) = 0.$

ALTERNATE GRAPHICAL METHOD

Basic Form. Another method for charting quite a general relationship between several variables can be developed from an equation of the form

$$\frac{f_1(u)}{f_2(v)} + \frac{f_3(w)}{f_4(t)} = 1 \tag{1}$$

Let OX and $O'Y$ be two parallel axes, any distance apart, and OO' a base line. Lay off the scales $m_1f_1(u)$ and $m_1f_2(v)$ on the OX axis with O as the point from which

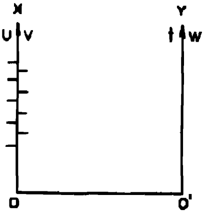

Fig. 29-131.

$$\frac{f_1(u)}{f_2(v)} + \frac{f_3(w)}{f_4(t)} = 1.$$

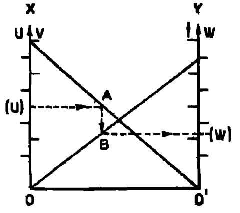

Fig. 29-132.

$$\frac{f_1(u)}{f_2(v)} + \frac{f_3(w)}{f_4(t)} = 1.$$

measurements are made. Similarly, lay off the scales $m_2f_3(w)$ and $m_2f_4(t)$ on the $O'Y$ axis measured from O' (Fig. 29-131). To find the value of one of the variables when values of the other three are given, follow the direction of the arrows in Fig. 29-132. For example, if values of u, v, and t are given, find the value of w (see Fig. 29-132).

1. Draw a line from O to t.
2. Draw a line from O' to v.

3. Draw a line from u parallel to OO' intersecting $O'v$ at A.
4. Draw a line from A parallel to the axis intersecting Ot at B.
5. Draw a line from B parallel to OO' intersecting the $O'Y$ axis at the value of w on the w scale.

It is evident that the value of any one of the variables may be found when the values of the other three are given.

$$f_1(u) + f_3(w) = f_2(v) \quad (1a)$$

If $f_2(v) = f_4(t)$, Eq. (1) takes the above form. The equations of the scales will be $mf_1(u)$, $mf_3(w)$, and $mf_2(v)$ (Fig. 29-133).

EXAMPLE: If $w = 3$ and $v = 8$, solve for u in the equation $2u + w = 10 \log v$ (Fig. 29-134). Let $m = \frac{1}{2}$. Then the scale equations will be u, $w/2$, and $5 \log v$.

The value of u is 3.01.

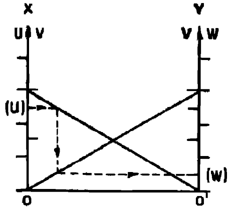

FIG. 29-133. $f_1(u) + f_3(w) = f_2(v)$.

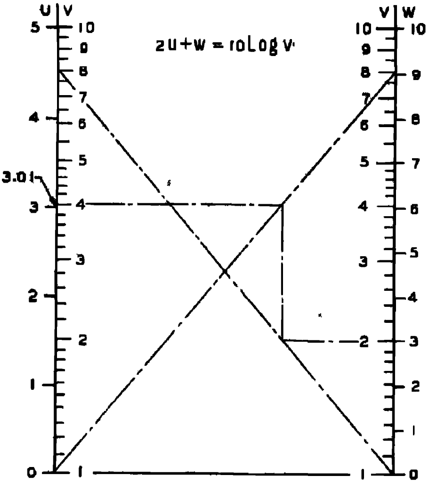

FIG. 29-134.

If lined paper is used, it is necessary only to lay off the v scale on one axis. A nomogram for this equation is shown in Fig. 29-59.

$$\frac{1}{f_2(v)} + \frac{1}{f_4(t)} = \frac{1}{f_3(w)} \qquad (1b)$$

If $f_3(w) = f_1(u)$, Eq. (1) takes this form. Since the w scale is the same on both axes, it is necessary only to lay it off on one axis.

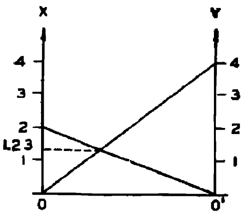

FIG. 29-135. $\frac{1}{V} + \frac{1}{T} = \frac{1}{W}$.

As an example of this type consider the equation (Fig. 29-135)

$$\frac{1}{V} + \frac{1}{T} = \frac{1}{W}$$

A chart for the equation $(1/2V) + (1/3T) = 1/U$ is shown in Fig. 29-136. When $T = 2$ and $V = 3$, $U = 3$.

A chart for the equation $[1/2(V - 1)] + [1/3(T + 1)] = 1/(U - 2)$ is shown in Fig. 29-137. When $T = 2$ and $V = 4$, $U = 5.6$.

$$\frac{f_5(R) \cdot f_1(u)}{f_2(v)} + \frac{f_6(S) \cdot f_3(w)}{f_4(t)} = 1 \tag{1c}$$

For this case $f_5(R)$ and $f_6(S)$ can be considered as scale multipliers for $f_1(u)$ and $f_3(w)$, respectively. The resulting form of chart will consist of a series of parallel scales

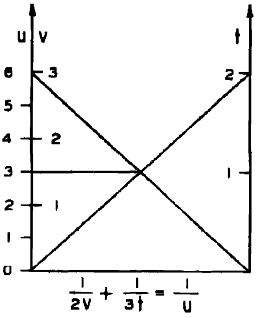

FIG. 29-136. $\frac{1}{2V} + \frac{1}{3T} = \frac{1}{U}$.

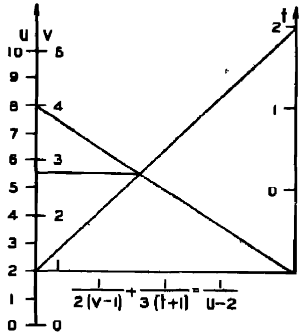

FIG. 29-137.

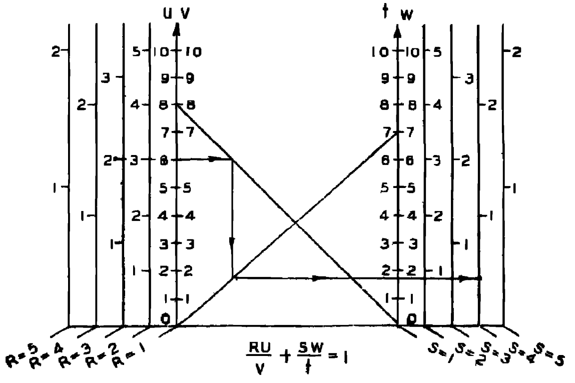

FIG 29-138

for the range of values of R and S. The series of scales may be replaced by a network. This process will be illustrated by a simple example.

Consider the equation

$$(RU/V) + (SW/T) = 1$$

On the left lay off the scales RU, at equal intervals from $R = 1, 2, 3, \ldots$, the consecutive scales being U, $2U$, $3U$, . . . (Fig. 29-138). Similarly, the scales for SW are constructed on the right-hand side. Now pass a curve (straight line in this case) through the same numbers on the scales, with a resulting network as in Fig. 29-139. When $U = 1.07$, $S = 3$, $T = 10$, $V = 8$, $R = 3$; then $W = 2$.

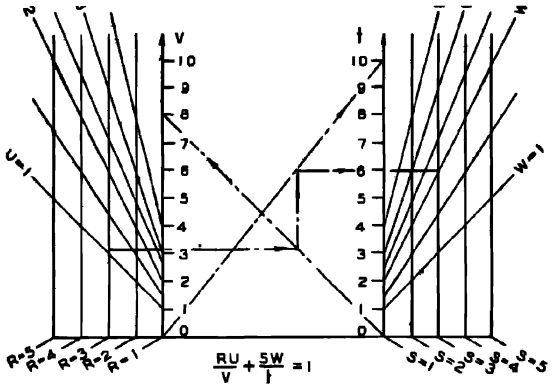

FIG. 29-139.

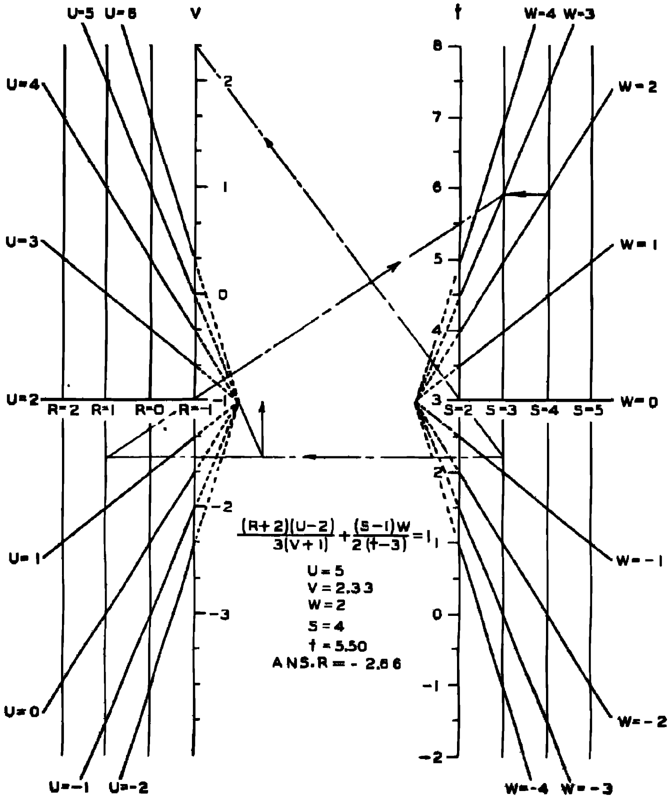

FIG. 29-140.

Two additional charts are illustrated to show the possibilities of this type of representation (Fig. 29-140):

$$\frac{(R+2)(U-2)}{3(V+1)} \qquad \frac{(S-1)W}{2(T-3)}$$

Example: Given $T = 5.5$, $V = 2.33$, $S = 4$, $W = 2$, and $U = 5$, find R.

Draw cross lines to $T = 5.5$ and $V = 2.33$. Locate point where $S = 4$ and $W = 2$. Draw horizontal line from this point to the cross line, then down to the other cross line and across until it intersects the $U = 5$ line; then project it up to the R-axis where it is estimated that $R = -2.66$.

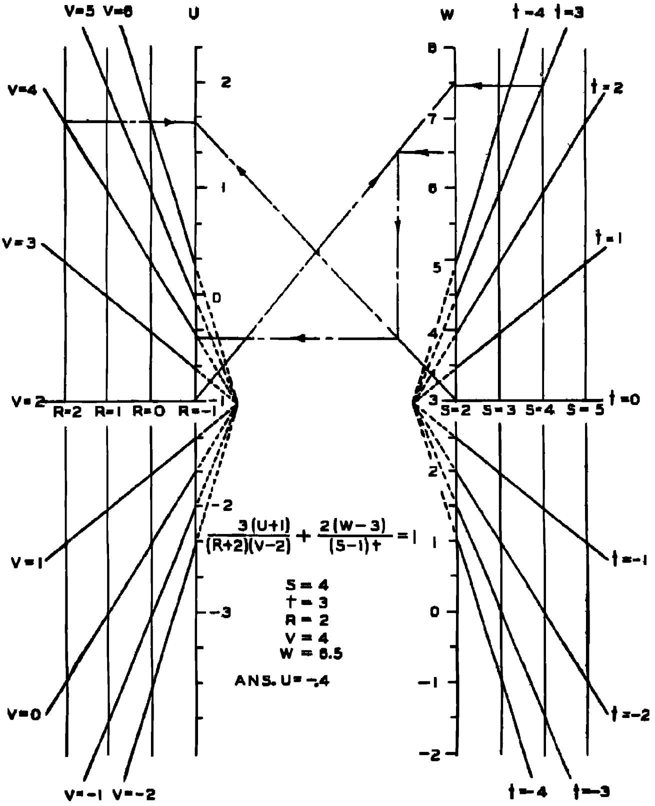

Fig. 29-141.

The R and S scales would be continued in both directions on a finished chart (Fig. 29-141).

$$\frac{3(U+1)}{(R+2)(V-2)} + \frac{2(W-3)}{(S-1)T} = 1$$

The structure of this chart is the same as the equation for Fig. 29-140 above, with the U lines replaced by V lines and the W lines by T lines.

$$f_1(u)/[f_7(Q)][f_5(R)][f_2(v)] + f_3(w)/[f_6(S)][f_4(t)] \tag{1d}$$

As an example of this type consider the equation

$$\frac{10U}{RQV} + \frac{5W}{ST} \quad 1$$

This equation may be written as

$$\frac{(10/R)U}{QV} + \frac{(5/S)W}{T} \quad 1$$

Here again consider $10/R$ and $5/S$ to be the multiplying factors of U and W, respectively. The completed chart will consist of a network of straight lines and hyperbolas on the left and a family of hyperbolas on the right (Fig. 29-142). An example is shown on the chart.

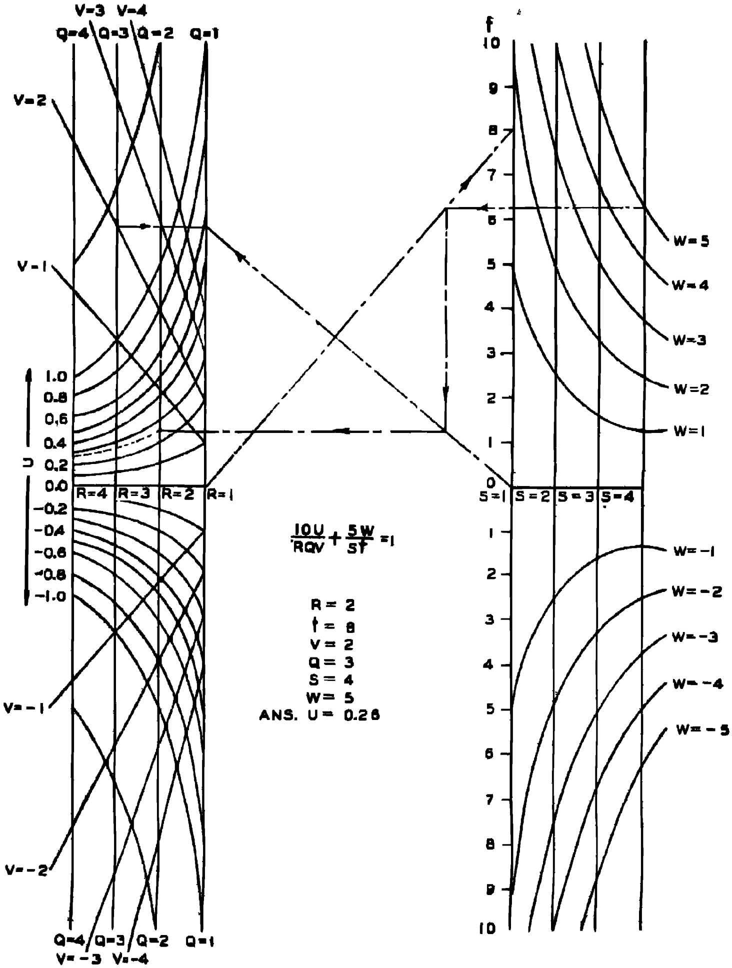

Fig. 29-142.

It is to be noticed that, if the equation is rewritten as

$$\frac{(10/R)U}{QV} + \frac{5W}{ST} = 0$$

S is a scale multiplier of T, and a family of straight lines for T replaces the W curves.

$$\frac{f_1(u)}{f_2(v)} + f_3(w) = 1 \qquad \text{or} \qquad f_1(u) + f_2(v)[f_3(w) - 1] = 0 \tag{1e}$$

This equation is a result of Eq. (1) when $f_4(t) = 1$. The t scale is replaced by a fixed point, and one of the cross lines is fixed (Fig. 29-143).

$$f_1(u) + f_3(w) = 1 \tag{1f}$$

This equation follows from Eq. (1) when $f_2(v) = 1$ and $f_4(t) = 1$. The t and v scales are replaced by two fixed cross lines (Fig. 29-144).

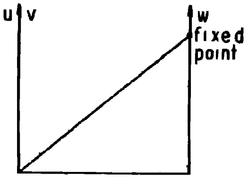

FIG. 29-143. $\frac{f_1(u)}{f_2(v)} + f_3(w) = 1.$

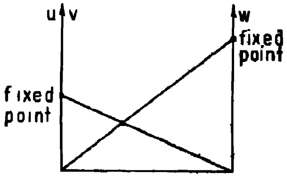

FIG. 29-144. $f_1(u) + f_3(w) = 1.$

Notice that the equation $f_5(R) \cdot f_1(u) + f_6(S) \cdot f_3(w) = 1$ could be charted by adding a network on either side.

This type of chart can be extended to an unlimited number of variables or can be used in conjunction with nomograms. For example, consider the equation

$$\frac{1}{v} + \frac{1}{t} = \frac{z}{w} \qquad \text{or} \qquad wt + vw = vt$$

Let $z/w = 1/Q$; then $(1/v) + (1/t) = 1/Q$, and $Q/w = 1/z$. The form of the chart will be as indicated in Fig. 29-145.

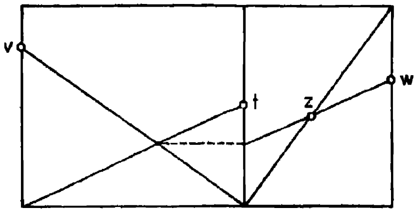

FIG. 29-145. $\frac{1}{v} + \frac{1}{t} = \frac{z}{w}.$

SIMPSON'S RULE

This is a method of finding the approximate area under a curve or finding the approximate value of a definite integral.

Given a curve, measure the ordinates spaced at intervals h apart (Fig. 29-146). The smaller the interval, the better the approximation. For an even number of intervals the area A is

$$A = (h/3)[y_0 + 4(y_1 + y_3 + \cdots + y_{n-1}) + 2(y_2 + y_4 + \qquad + y_{n-2}) + y_n]$$

where h is the distance between ordinates.

EXAMPLE 1: Find the area under the curve plotted from a table of values whose distances are measured in feet.

x	0	2	4	6	8	10	12	14	16	18	20
y	12.5	12.8	12.9	13.0	13.0	12.8	12.4	11.8	10.4	6.8	0.5

$$A = \tfrac{2}{3}[12.5 + 4(12.8 + 13.0 + 12.8 + 11.8 + 6.8) + 2(12.9 + 13.0 + 12.4 + 10.4) + 0.5] = 226.1 \text{ sq ft}$$

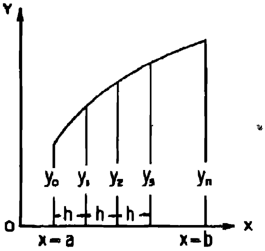

FIG. 29-146. Simpson's rule.

EXAMPLE 2: Find the value of $\int_2^{10} dx/x$. This is equivalent to finding the area under the curve $y = 1/x$ from $x = 2$ to $x = 10$. Divide the interval into eight parts. Then $h = 1$, and we obtain the following table of values.

x	2	3	4	5	6	7	8	9	10
y	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{1}{5}$	$\frac{1}{6}$	$\frac{1}{7}$	$\frac{1}{8}$	$\frac{1}{9}$	$\frac{1}{10}$

$$A = \tfrac{1}{3}[\tfrac{1}{2} + 4(\tfrac{1}{3} + \tfrac{1}{5} + \tfrac{1}{7} + \tfrac{1}{9}) + 2(\tfrac{1}{4} + \tfrac{1}{6} + \tfrac{1}{8}) + \tfrac{1}{10}] = 1.6109$$

HATCHET PLANIMETER

The hatchet planimeter consists essentially of a tracing point and a convex chisel edge rigidly connected, the point and the edge being in the same plane. When the point is moved along a curve, the edge describes a curve of pursuit (Fig. 29-147). This instrument is used to approximate areas. Let the tracer point O start from a point O within the area (Fig. 29-148) (preferably near its center), move along any line to the boundary, then along the boundary and back along the same line to O. The angle θ (between the direction of departure and the direction of return) is measured and converted into radians. The approximate area is

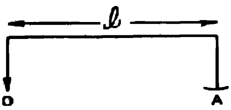

FIG. 29-147. Hatchet planimeter.

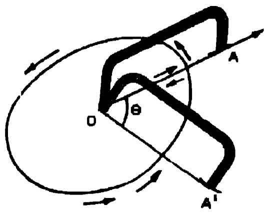

FIG. 29-148. Hatchet planimeter.

$$A = l^2\theta$$

The legs of the instrument must, at all times, be perpendicular to the horizontal plane of the paper on which the curve is drawn.

GRAPHICAL INTEGRATION

Evaluation of Integrals by Areas. It is desired to find the value of the definite integral $\int_a^b f(x)\,dx$ or the area under the curve $y = f(x)$, by a graphical method. Draw the curve $y = f(x)$ (Fig. 29-149), and along the ordinate at any point $P(x, y)$ lay off the distance y', which is the numerical value of the area bounded by the curve $y = f(x)$ and the ordinates $x = a$ and $x = x$, *i.e.*, $y' = \int_a^x f(x)\,dx$. Now for every point $P(x, y)$ there is a corresponding point $Q(x, y')$. The curve traced by the point Q is called the *integral* curve, and the curve traced by the point P is called the *derivative* curve.

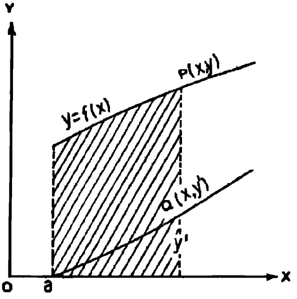

Fig. 29-149. Graphical integration.

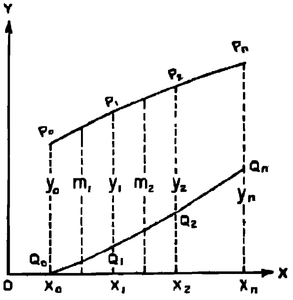

Fig. 29-150. Graphical integration.

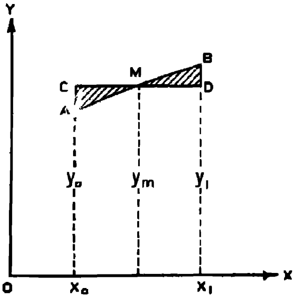

Fig. 29-151. Graphical integration.

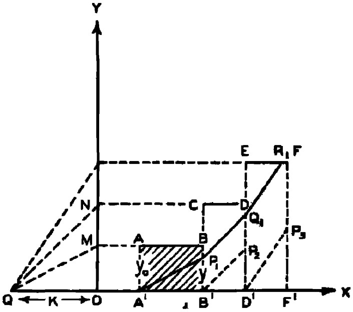

Fig. 29-152. Graphical integration.

To construct the integral curve:

1. Divide the interval from x_0 to x_n (Fig. 29-150) into n equal or unequal intervals and draw ordinates $y_0, y_1, \ldots, y_n$.

2. Measure the areas $x_0P_0P_1x_1 = x_1Q_1 = y_1'$, $x_0P_0P_2x_2 = x_2Q_2 = y_2'$, $\ldots$, $x_0P_0P_nx_n = x_nQ_n = y_n'$. These areas may be found by means of a planimeter or by the construction of mean ordinates. For example, the area $x_0P_0P_1x_1$ is equal to the area of a rectangle whose base is x_0x_1 and whose altitude is the mean ordinate m_1 within that area. Similarly, the area $x_1P_1P_2x_2$ is equal to the area of a rectangle whose base is x_1x_2 and whose altitude is the mean ordinate m_2.

The mean ordinate can be determined quite accurately by inspection since the mean ordinate y_m for the arc segment AB (Fig. 29-151) is determined by finding a

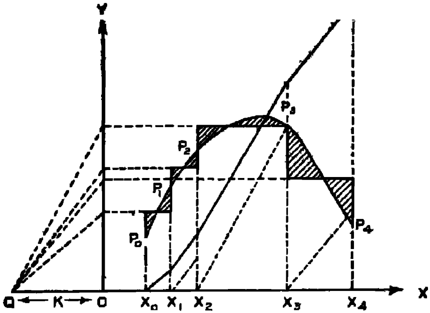

FIG. 29-153. Graphical integration.

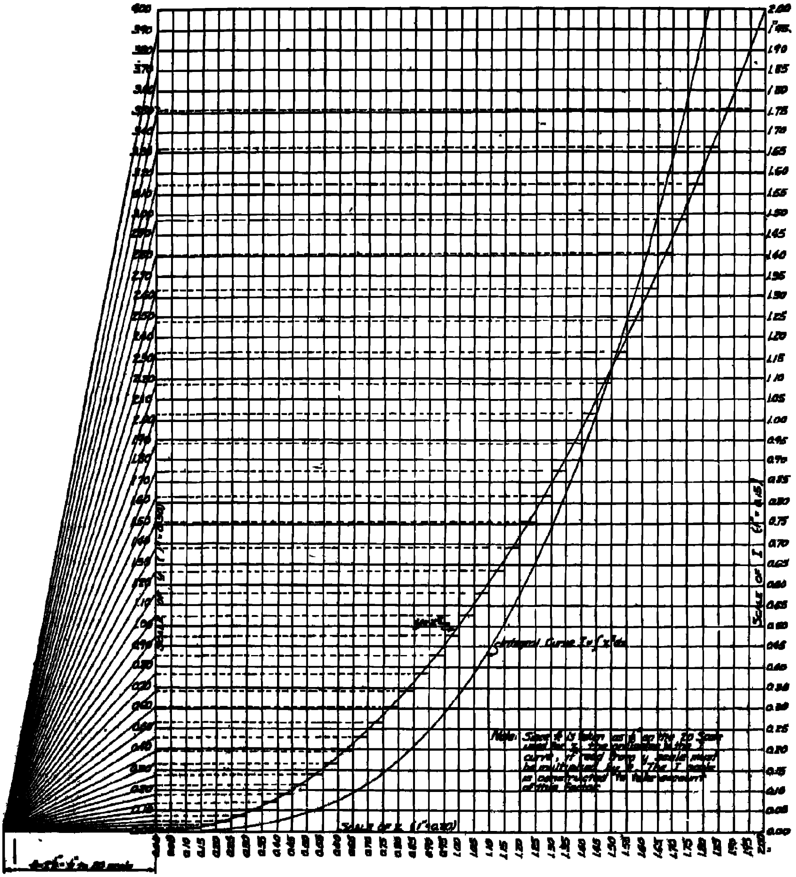

Note: Since K is taken as ... on the 20 Scale used for y, the ordinates to the I curve, if read from y scale must be multiplied by ... The I scale is constructed to take account of this factor.

FIG 29-154. Area under curve.

point M on the curve such that the area of the rectangle x_0CDx_1 is equal to the area under the arc segment AB or such that the shaded areas ACM and MBD are equal.

First consider the case when the derivative curve consists of a series of discontinuous straight lines parallel to the x-axis (Fig. 29-152). Choose a point Q at a convenient distance K from O. Extend AB to M on the y-axis, and draw MQ. Through A', the projection of A on the x-axis, draw $A'P_1$ parallel to MQ. The line $A'P_1$ is the integral curve of the line AB. Let $B'P_1 = y'$. Then by similar triangles

$$y'/y_0 = A'B'/K \qquad \text{or} \qquad y' = y_0(A'B')/K = 1/K \cdot (\text{area under } AB)$$

Similarly, $B'P_2$ is the integral curve for the line CD, and $D'P_3$ is the integral curve for the line EF. The broken line $A'P_1Q_1R_1$ is the integral curve of the broken line $ABCDEF$.

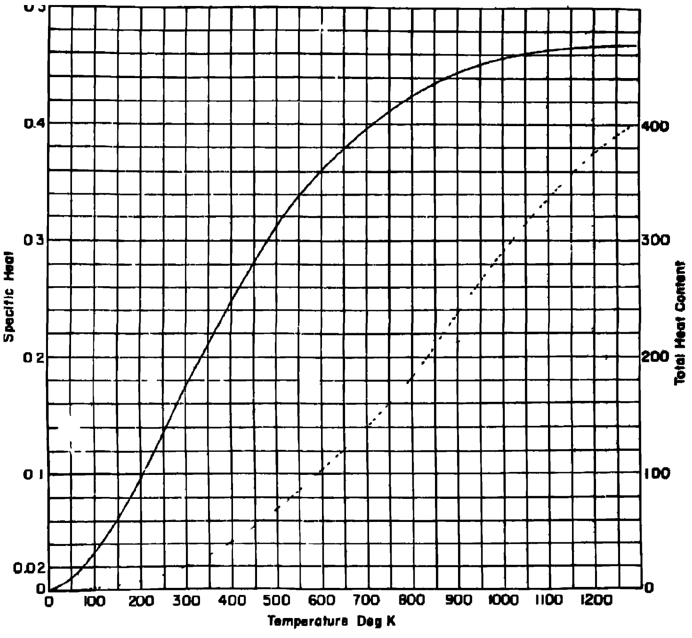

FIG. 29-155 Area under curve.

Now, consider a continuous curve (Fig. 29-153) Divide the interval from x_0 to x_1 into n parts, and draw ordinates at these points. Through $P_0, P_1, \ldots, P_n$ draw short vertical lines. Draw horizontal lines dividing each of the arcs $P_0P_1, P_1P_2, \ldots, P_{n-1}P_n$ into two parts such that the areas of consecutive shaded portions are equal (to the best approximation). Choose a suitable point Q at a distance K from O. The construction of a series of straight lines as in Fig. 29-153 represents approximately the envelope of the integral curve If the intervals x_ix_{i+1} are very small, the short sections of straight lines will approximate a continuous integral curve.

EXAMPLE 1: Find the area bounded by the curve $y = x^2$, the x-axis, and the line $x = 2$, by a graphical method. Check the result by performing the required integration.

The table of values and graphic solutions are shown in Fig. 29-154.

EXAMPLE 2. Given the graph of specific heat plotted against temperature, find the total heat content (Fig. 29-155).

Evaluation of Definite Integrals by Nomograms. If the value of the indefinite integral $\int f(x, a)\,dx$ is known, a nomogram can be made for values of the definite integral.

If the value of the indefinite integral is not known, but a table of values of the definite integral is available, then sometimes a nomogram can be made empirically.

Charts for the integrals

$$\int_{x_1}^{x_2} \tan x\,dx \qquad \int_0^x \frac{dx}{a^2 - x^2} \qquad \text{and} \qquad \int_0^{x_1} \frac{dx}{\sqrt{a + bx}}$$

are shown in Figs. 29-156*a*, 29-156*b*, 29-156*c*, respectively.

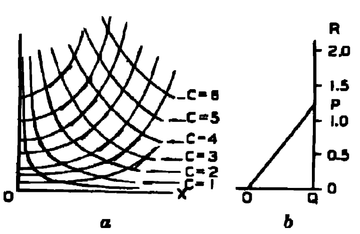
GRAPHICAL SOLUTION OF DIFFERENTIAL EQUATIONS

First-order Equation $dy/dx = f(x, y)$. If (x, y) are the coordinates of a point on a curve, then dy/dx is the slope of the tangent at that point. A differential equation of the first order $[dy/dx = f(x, y)]$ assigns a definite direction to every point (x, y) in the x, y-plane. If a family of curves can be found such that, at every point of every member, the differential equation is satisfied, then that family is called the integral family of curves of the differential equation.



a b

Fig. 29-157. $dy/dx = xy$.

Example 1: Solve the equation $dy/dx = xy$.

First sketch the curves $xy = c$ (for illustrating purposes only curves in the first quadrant will be drawn) (Fig. 29-157a).

In order to show the integral curves (Fig. 29-157a), it is convenient to draw a line OQ (Fig. 29-157b) parallel to the positive direction of the x-axis and of unit length and lay off on this line a uniform scale of modulus 1. The slope of any line OP is numerically equal to PQ units. Using Fig. 29-157b, it is easy to transfer a direction at various points of each curve in Fig. 29-157a. Curves are now shown having the slopes specified by a system of short strokes. These curves are approximations to the integral curves in the first quadrant.

Example 2: A graphical solution is shown for the equation $dy/dx = x - y^2$ (Fig. 29-158). Additional aids are noted to facilitate graphing:

1. Along the curve $x = y^2$, $dy/dx = 0$
2. Along the curve $1 - 2xy + 2y^3 = 0$, $d^2y/dx^2 = 0$

Solution of $dy/dx = f(x, y)$, with the Condition $x = x_0$, $y = y_0$. Determine the slope at (x_0, y_0), and draw a short stroke from (x_0, y_0) to the line $x_0 + h$, and read off the value of y_1 for $x = x_0 + h$. Now compute the slope at $(x_0 + h_1, y_1)$, and again draw a short stroke. If this process is continued and the intervals are small, these

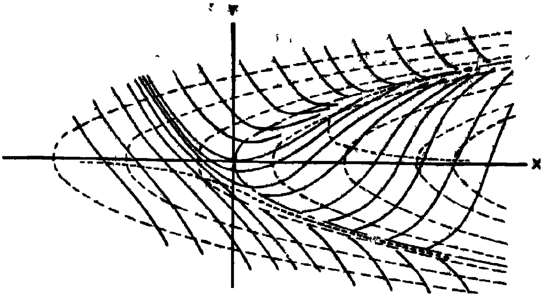


Fig. 29-158. $dy/dx = x - y^2$.

short lines will envelop a curve which is a good first approximation to the integral curve.

Graphical Solution of Two Simultaneous Equations of the First Order. Let the equations be

$$dz/dt = f_1(y, z, t) \tag{1}$$
$$dy/dt = f_2(y, z, t) \tag{2}$$

and when $t = t_0$, $y = y_0$, and $z = z_0$. Operate simultaneously with two sets of axes (Fig. 29-159).

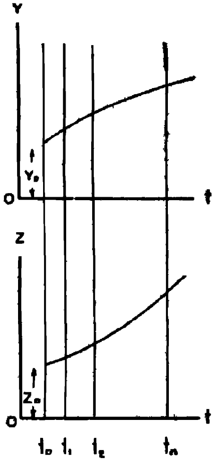

Fig. 29-159. $dz/dt = f_1(y, z, t)$, $dy/dt = f_2(y, z, t)$.

Solution of Higher Order Equations. An equation of the form

$$(d^2y/dx^2, dy/dx, y, x) = 0$$

subject to the conditions,

$$y = y_0 \qquad dy/dx = P_0 \text{ at } x = x_0$$

can be changed into the form,

$$d^2y/dx^2 = \phi(dy/dx, y, x)$$

Let $P = dy/dx$, then the original equation and its conditions become

$$dP/dx = \phi(P, y, x)$$
and
$$dy/dx = P$$

where $y = y_0$, and $P = P_0$ at $x = x_0$
Solve this pair of simultaneous equations as before.

EMPIRICAL EQUATIONS

When experimental data are obtained it is often necessary to formulate a relation between the variables in the form of an equation. From the observed data a graph is made on ordinary rectangular coordinate paper. Often the form of the curve will suggest the type of equation. However, we should choose an equation of as simple a form as possible. It is desirable to test the correctness of the form of the equation by writing the assumed equation in the form,

$$f(y) = a + b\phi(x) \qquad \text{or} \qquad Y = a + bX$$

where $Y = f(y)$ and $X = \phi(x)$ and plotting the points with (X, Y) as coordinates. If the points of this plot appear to lie on or near a straight line, then this line can be represented by the second form and hence the original curve by the first form.

Parabolic and Hyperbolic Curves $y = ax^b$ (Parabolic When $b > 0$ and Hyperbolic When $b < 0$). Parabolic curves pass through the points (0, 0) and (1, a), and as x increases, y increases. Hyperbolic curves pass through the point (1, a) and have the coordinate axes as asymptotes; and as one of the variables increases, the other decreases.

The method of verifying whether the data can be approximated by an equation of the form $y = ax^b$ is to take logarithms of both members of the equation. We obtain

$$\log y = b \log x + \log a$$

The plot of ($\log x$, $\log y$) on rectangular coordinate paper or (x, y) on logarithmic paper will be a straight line.

Consequently, *if a set of data can be approximately represented by an equation of the form* $y = ax^b$, *then the plot of* ($\log x$, $\log y$) *on rectangular coordinate paper or* (x, y) *on logarithmic paper approximates a straight line.*

Exponential Curves, $y = ae^{bx}$. Curves of this type pass through the point (0, a) and have the x-axis as asymptotes.

If a set of data can be approximately represented by an equation of the form $y = ae^{bx}$, *then the plot of* (x, $\log y$) *on rectangular coordinate paper or* (x, y) *on semilogarithmic paper approximates a straight line.*

Parabolic or Hyperbolic Curves, $y = a + bx^n$ (Where n Is Known). *If a set of data can be represented by an equation of the form* $y = a + bx^n$, *then the plot of* (x^n, y) *on rectangular coordinate paper approximates a straight line.*

Hyperbolic Curves, $y = a/(a + bx)$, $x/y = a + bx$, or $1/y = (a/x) + b$. This equation represents a hyperbola with asymptotes $x = -a/b$ and $y = 1/b$. *If a set of data can be approximately represented by an equation of the form* $y = a/(a + bx)$, *then a plot of* (x, x/y) *on rectangular coordinate paper or* (x, y) *on reciprocal paper approximates a straight line.*

Parabolic or Hyperbolic Curves, $y = ax^b + c$. Choose two points (x_1, y_1) and (x_2, y_2) on the curve sketched to represent the data. Locate a third point on the curve such that $x_3 = \sqrt{x_1x_2}$, and measure the ordinate at that point, which is y_3. Find the value of c from the equation

$$c = \frac{y_1y_2 - y_3^2}{y_1 + y_2 - 2y_3}$$

If a set of data can be approximately represented by an equation of the form $y = ax^b + c$, *then a plot of* $\log x$, $\log (y - c)$ *on rectangular coordinate paper or of* (x, $y - c$) *on logarithmic paper approximates a straight line.*

Exponential Curves, $y = ae^{bx} + c$. Choose two points (x_1, y_1) and (x_2, y_2) on the curve. Locate a third point on the curve such that $x_3 = \frac{1}{2}(x_1 + x_2)$, and measure the ordinate at that point which is y_3. Determine c from the equation used in the previous case.

If a set of data can be approximately represented by an equation of the form $y = ae^{bx} + c$, *then a plot of* x, $\log (y - c)$ *on rectangular coordinate paper or of* (x, $y - c$) *on semilogarithmic paper approximates a straight line.*

Parabola, $y = a + bx + cx^2$. *If a set of data can be approximately represented by an equation of the form* $y = a + bx + cx^2$, *then the plot of* [x, $(y - y_k)/(x - x_k)$], *where* (x_k, y_k) *are the coordinates of a point on the curve, will approximate a straight line.*

Hyperbolic Curves, $y = x/(a + bx) + c$. *If a set of data can be approximately represented by an equation of the form* $y = x/(a + bx) + c$, *then a plot of* [x, $(x - x_k)/(y - y_k)$], where (x_k, y_k) *are the coordinates of a point on the curve, will approximate a straight line.*

Logarithmic or Exponential Curves, $\log y = a + bx + cx^2$, or $y = ae^{bx+cx^2}$. *If a set of data can be approximately represented by an equation of the form* $\log y = a + bx + cx^2$, *then the plot of* $\left(x, \dfrac{\log (y/y_k)}{x - x_k}\right)$ *where* (x_k, y_k) *is a point on the curve, will approximate a straight line.*

VIBRATION*

BY WINSTON M. DUDLEY, SC.D.

Associate Director, Engineering Research Department, Standard Oil Company (Indiana), Formerly Associate Professor of Engineering Mechanics, Case Institute of Technology, Member ASME, SAE

FREE VIBRATIONS WITHOUT DAMPING

In order to be capable of executing vibrations, a physical system must contain mass and a restoring force, such as a spring. That is, if the system is moved from equilibrium in any direction, forces urging it back must be developed.

Figure 30-1 shows the simple case of a mass of weight W suspended on a coil spring whose rate is k lb per in. of deflection. The mass is supposed to be constrained so that it can move only in a vertical direction without rotation.

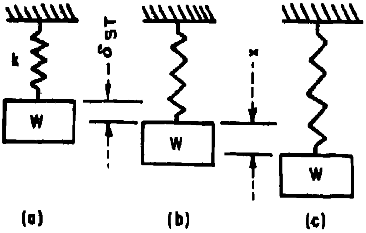

FIG. 30-1. Elementary system for free vibrations without damping.

Figure 30-1*b* shows the system at rest. The spring will be stretched an amount δ_{st} beyond its free length as indicated in Fig. 30-1*a*. This "statical deflection" $\delta_{st} = W/k$, since the weight must be supported, and equilibrium will occur when $k\delta_{st} = W$.

A vibration can be started by giving the weight initial velocity, by moving it to another position and releasing it, or both The additional deflection is denoted by x, as shown in Fig. 30-1*c*.

A mathematical solution for all possible motions can be obtained. Figure 30-2*a* shows a "free-body diagram" of the forces on the mass when it is in the deflected position, as in Fig. 30-1*c*. Since $W = k\delta_{st}$, the statical forces can be omitted, giving the simplified picture of Fig. 30-2*b*. (This is the reason for measuring x from equilibrium position.) The acceleration of the mass is d^2x/dt^2; since x is positive downward, this is also the positive direction for acceleration. Summation of vertical forces gives

$$(W/g)(d^2x/dt^2) = -kx \qquad (1)\dagger$$

the minus sign being due to the fact that the spring force acts upward for positive x. Thus, the acceleration will be negative when x is positive, indicating that the spring is trying to return the weight to equilibrium position. When the weight is above equilibrium position, x is negative and the acceleration is positive, a correct result.

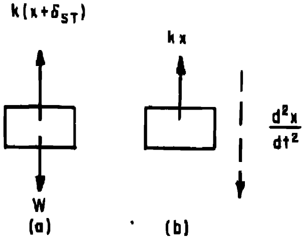

FIG. 30-2. Free-body diagram for mass in Fig. 30-1.

If initial conditions are given as $x = x_0$, $dx/dt = v_0$ when $t = 0$, the general solution of the differential equation (1) is

$$x_0 \cos \omega_n t + (v_0/\omega_n) \sin \omega_n t \qquad (2)$$

where

$$\omega_n^2 = kg/W. \qquad (3)$$

---

* Superior numbers refer to specific references listed at the end of this section.

† These numbers are for convenience in referring to the formulas.

This may be checked by substituting Eq. (2) in Eq. (1). By means of trigonometric identities, Eq. (2) can be put in the equivalent form:

$$x = A \cos (\omega_n t - \beta) \tag{4}$$

where $A = \sqrt{x_0^2 + (v_0/\omega_n)^2}$ and $\beta = \tan^{-1} (v_0/\omega_n x_0)$ (5)

The system will always require a constant time T to complete one full cycle of the vibration; T is known as the period. As the trigonometric functions in Eq. (2) repeat their values whenever $\omega_n t$ increases by 2π, we have

$$\omega_n T = 2\pi \qquad \text{or} \qquad T = \frac{2\pi}{\omega_n} = 2\pi \sqrt{\frac{W}{kg}} = 2\pi \sqrt{\frac{\delta_{st}}{g}} \quad \text{sec} \tag{6}$$

The "natural frequency" f_n is the number of cycles per second, which is the reciprocal of the period. Thus,

$$f_n = \frac{1}{T} = \frac{\omega_n}{2\pi} = \frac{1}{2\pi} \sqrt{\frac{kg}{W}} = \frac{1}{2\pi} \sqrt{\frac{g}{\delta_{st}}} \quad \text{cps} \tag{7}$$

Figure 30-3 shows a plot of Eq. (5), with the position of the weight shown vs. time. The quantity A is called the *amplitude* of the vibration, and the "peak to peak," or distance between the extreme positions, is called the *double amplitude*, or $2A$.

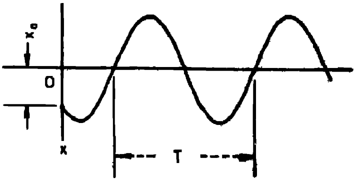

FIG. 30-3. Plot of free vibration (x vs. t).

NUMERICAL EXAMPLES: 1. A weight of 50 lb falls a distance of 2 ft from rest and then makes contact with a coil spring whose $k = 100$ lb per in. Find the greatest deflection of the spring.

SOLUTION: $\delta_{st} = W/k = 50/100 = 0.5$ in. Since the vibration starts with the weight above equilibrium position, $x_0 = -\delta_{st} = -0.5$ in. From elementary physics, the velocity developed by a 2-ft fall is found from $v_0^2 = 2gh = 2(32.2 \times 12)(2 \times 12) = 18{,}530$; hence $v_0 = 136$ in. per sec. From Eq. (3)

$$\omega_n = \sqrt{kg/W} = \sqrt{(100 \times 386)/50} = 28.2 \text{ radians/sec}$$

From Eq (5), $A = 4.85$ in. Thus the weight will reach a position 4.85 in. below *equilibrium* position, and the greatest compression of the spring will be $4.85 + 0.5 = 5.35$ in

2. An elevator car is observed to oscillate vertically with a double amplitude of ¼ in. and a frequency of 2 cps If the car weighs 6,000 lb, find the spring rate of the supports and the maximum tension developed in them.

SOLUTION: From Eq. (7), $\omega_n = 2\pi f_n = 2 \times 3.14 \times 2 = 12.57$ radians per sec. From Eq. (3),

$$k = (W/g)\omega_n^2 = (6{,}000/386)(12.57)^2 = 2{,}460 \text{ lb per in.}$$

Since the double amplitude $= 2A = 0.25$ in., $A = 0.125$ in., which is the maximum dynamic stretch in the cable. This causes a dynamic force of $kA = 2{,}460 \times 0.125 = 307$ lb. As the cable is already supporting the 6,000-lb car weight as a static load, the maximum tension is 6,307 lb.

EFFECT OF FRICTIONAL FORCES

Dry Friction. If the system of Fig. 30-1 must work against dry sliding friction, as in guides, the amplitude of a free vibration will decrease by a constant amount for each cycle, as shown in Fig. 30-4. The motion disappears entirely as soon as the weight comes to rest in a position in which the spring force is too small to overcome the friction.[1]

Velocity-squared Damping. Many actual systems are damped by fluid friction, in which the resistance is approximately proportional to the square of the velocity. Air friction, although very slight, is of this type. The mathematical treatment is difficult, resulting in infinite series representing hitherto unknown functions. The solutions, with tables complete enough for practical purposes, have been given by

Milne,[3,4,5] who had in view the problem of oscillations of water in the long pipes leading to hydroelectric plants.

With Milne's tables, any free vibration with velocity-squared damping can be plotted, one-half cycle at a time. He shows that the same mathematical results apply to all such systems, regardless of the relative values of weight, spring rate, and friction characteristic. The period of the oscillations is not constant but approaches the value for the undamped system at small amplitudes. Under such conditions, the friction force becomes insignificant, being proportional to the square of a small quantity; the vibration then continues for a long time. This occurs, for instance, in a piano string when struck; the amplitude diminishes rapidly at first, then more slowly, the string continuing to vibrate for thousands of cycles. Owing to the relatively weak friction, the pitch of the string is not changed even for large amplitudes. Another example occurs in the undulations of liquid in an open container; large amplitudes disappear rapidly, but small motions persist for a long time.

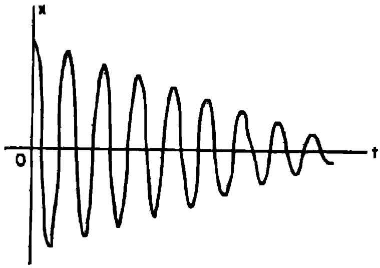

Fig. 30-4. Plot of free vibration damped by dry friction. (Amplitude decreases at constant rate with time.)

Damping Proportional to Velocity. If friction proportional to the first power of the velocity is assumed, an exact mathematical solution is easily obtained. The results have practical importance in the design of indicating instruments and vehicle suspensions. Figure 30-5 shows such a system. It is again assumed that the mass has vertical motion only, with a total spring constant k. The damping force, represented by a dashpot, equals $c\,dx/dt$. Figure 30-5*b* shows the free-body diagram, the weight again being eliminated by measuring x from the equilibrium position. The differential equation (summation of vertical forces) becomes

$$\frac{W}{g}\frac{d^2x}{dt^2} \qquad -kx - c\frac{dx}{dt} \qquad\qquad \frac{W}{g}\frac{d^2x}{dt^2} + c\frac{dx}{dt} + kx = 0 \tag{8}$$

Analysis of this equation by the usual methods shows that the system may have three different types of behavior, depending on the relative magnitude of the damping force. There is a "critical" value c_c for the damping. Letting $\omega_n{}^2 = kg/W$ as before and introducing

$$c_c = 2\sqrt{kW/g} = 2(W/g)\omega_n \tag{9}$$

there are three possible solutions, depending on whether c is greater than, equal to, or less than c_c. The equations are as follows:

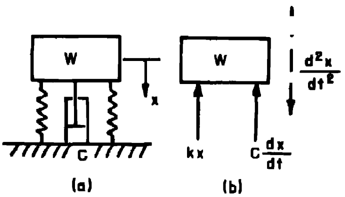

Fig. 30-5. System for free vibrations with viscous damping.

1. *More-than-critical Damping.* If $c > c_c$, there is overdamping. Let s_1 and s_2 be the two roots of the quadratic equation

$$\frac{W}{g}s^2 + cs + k = 0 \qquad\qquad s_{1,2} = \omega_n\left[\frac{c}{c_c} \pm \sqrt{\frac{c^2}{c_c{}^2} - 1}\right] \tag{10}$$

It can be seen that s_1 and s_2 will both be negative. The possible motions are given by

$$x = C_1e^{s_1t} + C_2e^{s_2t} \tag{11}$$

in which C_1 and C_2 are "constants of integration" whose values depend on the conditions assumed at $t = 0$. Thus the values of x are given by decreasing exponential functions, as shown in Fig. 30-6*a*. The system, if disturbed, does not oscillate but slowly creeps back to the central position. This is approximately the behavior of a door with a spring-and-dashpot closer attached.

2. *Critical Damping*. If $c = c_c$, there is critical damping. In this case,

$$s_1 = s_2 = -\omega_n$$

and the motion is given by

$$x = e^{-\omega_n t}(C_1 + C_2 t) \tag{12}$$

A plot of such a motion is shown in Fig. 30-6*b*. The motion is still not oscillatory, but it returns to equilibrium in less time than in Fig. 30-6*a*.

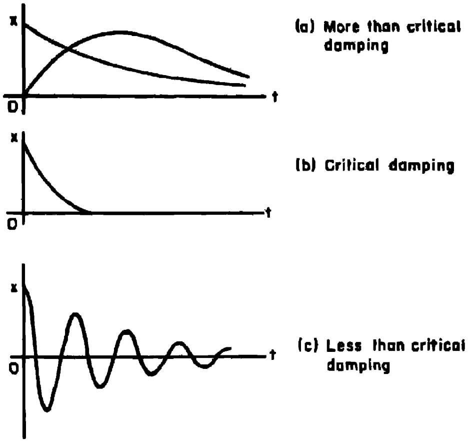

Fig. 30-6. Three types of possible motion with viscous damping.

3. *Less-than-critical Damping*. If $c < c_c$, there is less-than-critical damping. Introduce

$$q = \sqrt{\frac{kg}{W} - \frac{c^2g^2}{4W^2}} = \omega_n \sqrt{1 - \frac{c^2}{c_c^2}} \tag{13}$$

Then the possible motions are given by

$$x = e^{-(c/c_c)\omega_n t}(C_1 \cos qt + C_2 \sin qt) \tag{14}$$

As shown in Fig. 30-6*c*, a vibration of decreasing amplitude will occur. Most physical systems behave in this way; cases 1 and 2 do not usually arise unless damping is artificially increased by some means.

Correct Damping of Indicating Instruments. Proper application of the above principles is essential in the design of automatic controls or indicating instruments, such as grocery scales or electric voltmeters and ammeters. The indicating element in such cases has mass and is urged toward an equilibrium position by springs or pendulum action. When a load is applied, the location of the equilibrium position is shifted. It is seen that the most satisfactory results will occur if the system is critically damped (or slightly underdamped) as in case 2. The indicator will then go to its new position in the least possible time, without oscillations. If the system is too much underdamped, the needle will swing for some time before coming to rest, while with overdamping, it will only creep slowly toward its final reading.

Grocery scales are usually provided with an adjustable oil dashpot, so that the weight indication will be approached smoothly in the minimum time. Electric meters may have damping in the form of air paddles or a nonmagnetic metal disk moving between the poles of a magnet. In the latter case, motion of the conducting disk through the magnetic field generates eddy currents, which convert the vibration energy into heat. When the system is stationary, no force is exerted, and the indication is not affected. This is the only practical case in which damping proportional to the first power of the velocity is regularly found (except in a-c electric circuits). The same magnetic principle is used in the common automobile speedometer to give an indication of speed.

PENDULUM SYSTEMS

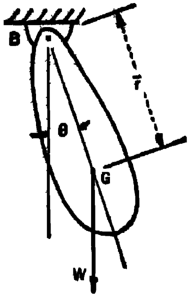

FIG. 30-7. Compound pendulum.

Figure 30-7 shows a "compound pendulum," *i.e.*, one which has distributed mass. Let W be the weight, G the center of gravity, $\bar{r}$ the radius from the swing point to G, and I_B the moment of inertia of the body around the bearing B. Taking moments around B, the equation of motion is

$$I_B(d^2\theta/dt^2) = -W\bar{r}\sin\theta \qquad (15)$$

For small angles, $\sin\theta$ may be approximated by θ (in radians). The equation is then similar to Eq. (1); $\omega_n{}^2$ becomes $W\bar{r}/I_B$, and the natural frequency is

$$f_n = (1/2\pi)\sqrt{W\bar{r}/I_B} \quad \text{cps} \qquad (16)$$

If the pendulum is reduced to a point mass W at the end of a string of length $\bar{r}$, $I_B = W\bar{r}^2/g$ and $f_n = (1/2\pi)\sqrt{g/\bar{r}}$, a familiar result in physics.

ROCKING CHAIR, CYLINDER IN TROUGH, ETC.

Figure 30-8 represents a number of possible vibratory systems, such as a rocking chair, a cylinder rolling in a trough of larger radius, etc. The moving element has a surface of radius r, and its center of gravity is at a distance h above the bottom. Its moment of inertia about a transverse axis through G is I_G. The trough radius is R. It can be shown that, if the moving element rolls without slipping, the natural frequency is

$$f_n = \frac{1}{2\pi}\sqrt{\frac{W(Rr - Rh + rh)}{(R - r)\left(I_G + \frac{W}{g}h^2\right)}} \quad \text{cps} \qquad (17)$$

If the motion takes place on a level floor, $R = \infty$ and the equation becomes

$$f_n = \frac{1}{2\pi}\sqrt{\frac{W(r - h)}{I_G + \frac{W}{g}h^2}} \quad \text{cps} \qquad (18)$$

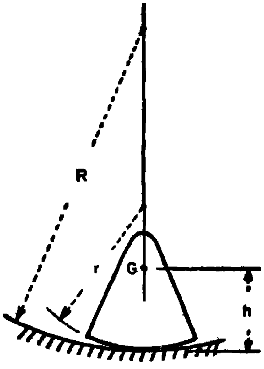

FIG. 30-8. Rocking chair, cylinder in trough, etc.

FORCED VIBRATIONS WITHOUT DAMPING

Figures 30-9, 30-10, and 30-11 show three cases in which a simple system is subject to alternating forces which compel it to vibrate at a frequency different from its natural frequency. In Fig. 30-9, the mass is acted on by a simple harmonic force $P_0 \sin\omega t$, such as might be caused by magnetic action with alternating current. In Fig. 30-10, the foundation is vibrating with an amplitude $a_0 \sin\omega t$. In Fig. 30-11, the weight carries a rotating member on which there is a small unbalanced weight W_1 at a radius r. If the rotor turns at N rpm, its rate of turning in radians per second is $\omega = 2\pi N/60$, and the centrifugal force on W_1 is $(W_1/g)r\omega^2$. The vertical component of this force is then $(W_1/g)r\omega^2 \sin\omega t$.

In all three cases, it is assumed that the mass W is guided so that only vertical motions can occur. Taking summation of vertical forces in each case, the differential equations of motion are

$$(W/g)(d^2x/dt^2) + kx = P_0 \sin \omega t \qquad \text{(Fig. 30-9)} \tag{19}$$
$$(W/g)(d^2x/dt^2) + kx = ka_0 \sin \omega t \qquad \text{(Fig. 30-10)} \tag{20}$$
$$(W/g)(d^2x/dt^2) + kx = (W_1/g)r\omega^2 \sin \omega t \qquad \text{(Fig. 30-11)} \tag{21}$$

It is seen that the equations are identical except for the meaning attached to the constants on the right-hand side.

All the systems are still capable of executing free vibrations as in Eqs. (4) and (7). However, in actual systems, such free vibrations are soon damped out by friction. Thus, the forced vibrations are the only ones of practical importance, unless transient conditions must be studied, as in the case of a spring-supported vehicle passing over a bump.

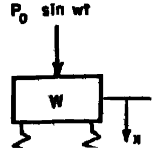

FIG. 30-9. Forced vibration without damping (constant amplitude of disturbing force).

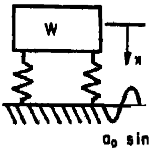

FIG. 30-10. Forced vibration caused by vibrating foundation.

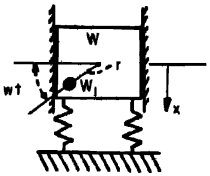

FIG. 30-11a. Forced vibration caused by rotating or reciprocating unbalanced mass (amplitude of disturbing force proportional to square of speed).

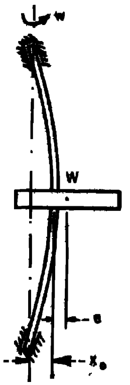

FIG. 30-11b. Deflection of flexible shaft caused by rotating unbalance.

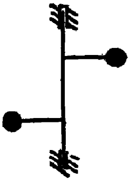

FIG. 30-11c. Dynamic unbalance.

Introduce $\omega_n^2 = kg/W$ as before. It is easily verified by substitution that the forced vibrations in the preceding cases are

$$x = \frac{P_0}{k}\frac{1}{1 - (\omega^2/\omega_n^2)} \sin \omega t \qquad \text{(Fig. 30-9)} \tag{22}$$

$$x = a_0 \frac{1}{1 - (\omega^2/\omega_n^2)} \sin \omega t \qquad \text{(Fig. 30-10)} \tag{23}$$

$$x = \frac{W_1 r}{W}\frac{(\omega^2/\omega_n^2)}{1 - (\omega^2/\omega_n^2)} \sin \omega t \qquad \text{(Fig. 30-11)} \tag{24}$$

In Fig. 30-10, let y be the amount of compression in the spring. Then

$$y = x - a_0 \sin \omega t$$

Substituting Eq. (23) for x,

$$y = a_0 \frac{(\omega^2/\omega_n^2)}{1 - (\omega^2/\omega_n^2)} \sin \omega t \tag{25}$$

Figure 30-11b shows a case closely related to Fig. 30-11a. A shaft is supported in bearings and turns with an angular velocity of ω radians per sec. It carries a disk of weight W whose center of gravity is displaced a distance e from the shaft center. The spring constant of the shaft in the lateral direction (at the location of the disk) is k lb/in. The problem is to find the amount x_0 by which unbalanced centrifugal force will deflect the shaft. As the center of gravity of the disk is moving in a circle of radius $x_0 + e$, the summation of forces gives

$$(W/g)(r_0 + e)\omega^2 = kx_0 \tag{21a}$$

Using $\omega_n^2 = kg/W$ and solving for x_0,

$$x_0 = e\frac{(\omega^2/\omega_n^2)}{1 - (\omega^2/\omega_n^2)} \tag{24a}$$

Thus, the magnitudes of important quantities in these vibrations depend on the expressions $\frac{1}{1 - (\omega^2/\omega_n^2)}$ and $\frac{(\omega^2/\omega_n^2)}{1 - (\omega^2/\omega_n^2)}$. These are known as "magnification factors" and are plotted against ω/ω_n in Figs. 30-12 and 30-13.

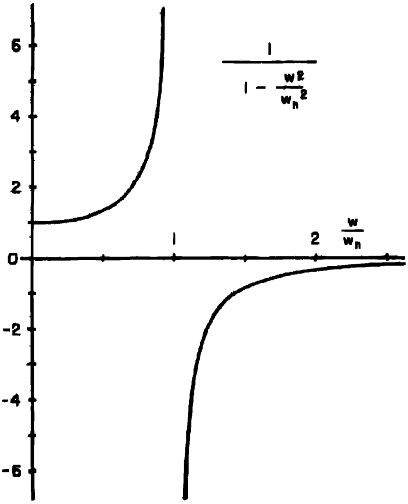

FIG. 30-12. Magnification factor for forced vibration (see Fig. 30-9).

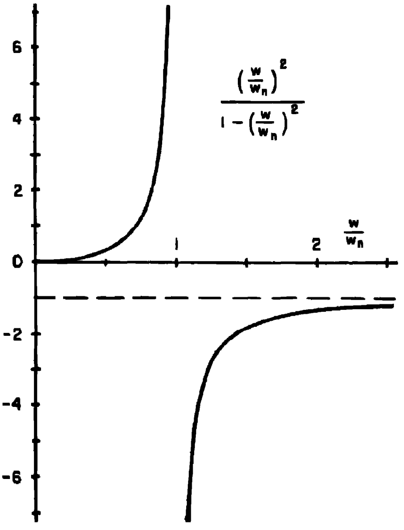

FIG. 30-13. Magnification factor for forced vibration (see Fig. 30-11a).

Figure 30-12 shows that the amount of vibration built up by the disturbing forces in Figs. 30-9 or 30-10 depends to a large extent on the ratio ω/ω_n or f/f_n of the disturbing frequency to the natural frequency. Three general regions or types of response can be noted.

1. Where the disturbing frequency is slow compared to the natural frequency, there is little inertia effect. In Fig. 30-9, a constant force P_0 would deflect the spring an amount P_0/k. At slow disturbing frequencies, the suspended mass will move slowly through cycles of this amplitude. In Fig. 30-10, at slow frequencies not much inertia force will be developed; the spring will remain of nearly constant length, and the whole system will move up and down with an amplitude a_0.

2. As the disturbing frequency approaches the natural frequency, very large vibrations can be built up; this is known as "resonance." The infinite amplitudes shown in Figs. 30-12 and 30-13 arise because friction was neglected in the analysis and because it was assumed that unlimited deflections may occur in the springs. In practice, neither of these assumptions is correct. Friction or "bottoming" of the springs may hold the amplitude to a finite value; the springs may not retain their linear force-deflection characteristic at high deflections; or breakage may occur.

3. When the disturbing frequency is well above the natural frequency, vibration is held to a small value by the inertia of the mass. That is, the weight tends to remain stationary because the disturbing force changes direction so rapidly that the weight does not have time to build up velocity in one direction.

Vibration caused by rotating or reciprocating unbalanced weight, as in Figs. 30-11a or 30-11b, occurs many times in practice. The response curve (Fig. 30-13) shows that, at slow rotational speeds, the centrifugal force is small, and not much vibration or bending of the shaft occurs. At resonance, violent motions may take place. At still higher speeds, the center of gravity tends to remain stationary in space, forcing the springs or the shaft to accommodate themselves; *i.e.*, W_1r/W and e represent the amount by which the center of gravity is displaced from the center of rotation if W_1 is small compared to W. At high speeds the magnification factor approaches -1, showing that the shaft center moves outside to permit the center of gravity to remain nearly stationary in space.

TYPES OF UNBALANCE IN ROTORS

The condition of the rotor in Fig. 30-11*b* is known as static unbalance, as it can be detected by laying the shaft on smooth horizontal rails; the heavy side will go to the bottom. Thin disks, such as turbine wheels and the balance wheels of watches, can be balanced in this way. In longer elements, such as crankshafts and electric-motor armatures, a more troublesome condition known as dynamic unbalance can occur. This is shown in Fig. 30-11c. Such a rotor is in static balance; but when run at high speed, it exerts strong shaking forces on its bearings. As the two centrifugal forces are not collinear, a force couple exists which can be balanced only by bearing reactions rotating with the shaft.

In order to correct dynamic unbalance, weights must be added or removed in at least two planes, as a couple can be counteracted only by an opposite couple. The correction locations should preferably be at the ends of the rotor and at the greatest possible radius, so as to minimize the weights required.

Some sort of balancing machine is necessary to measure the combination of static and dynamic unbalance which normally occurs in production rotors.

BALANCING MACHINES AND OTHER VIBRATION-MEASURING INSTRUMENTS

Formerly, most apparatus for measuring vibrations was mechanical. The accuracy required, and the lack of a mass market, made the equipment cumbersome and costly. In recent years, electric and electronic devices have largely taken over the field; they can be made relatively cheaply, and the use of amplifiers makes them far more sensitive than any mechanical arrangement can possibly be.

There are many such instruments now commercially available. Both old and new types are described in the general books by Timoshenko and Den Hartog.[1,2]

FORCED VIBRATION WITH VISCOUS DAMPING

In Fig. 30-14, a viscous dashpot has been added to Fig. 30-9. The frictional force (assumed proportional to the first power of the velocity) makes a considerable change in the behavior of the system. The summation of vertical forces now gives

$$\frac{W}{g}\frac{d^2x}{dt^2} + c\frac{dx}{dt} + kx = P_0 \sin \omega t \qquad (26)$$

In the steady state (no free vibrations), the motion of the mass is given by

$$x = A \sin (\omega t - \phi)$$

where

$$A = \frac{P_0}{k}\,\frac{1}{\sqrt{[1 - (\omega^2/\omega_n{}^2)]^2 + (2c\omega/c_c\omega_n)^2}} \qquad (27)$$

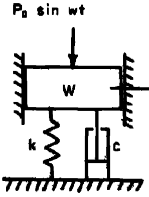

Fig. 30-14. Forced vibration with viscous damping.

ϕ is known as the phase angle, since it is that portion of 360 deg by which the x motion lags behind the disturbing force. The value of ϕ is

$$\phi = \tan^{-1} \frac{(2c\omega/c_c\omega_n)}{1 - (\omega/\omega_n)^2} \qquad (28)$$

The steps by which this solution is obtained are given in textbooks on vibration or differential equations.

Figures 30-15 and 30-16 show A and ϕ plotted against ω/ω_n. It is seen that the damping force prevents the amplitude from ever becoming infinite; also that the effect of damping on amplitude is not great except near resonance. Figure 30-16 shows the trend for the phase angle; it is small at low frequencies, passes through 90 deg at resonance, and approaches 180 deg at high frequencies. This can be demonstrated in a simple way by taking a string with a weight on one end and exciting the motion of the pendulum by moving the point of support from side to side. If the support point is oscillated at less than the natural frequency of the pendulum, the appearance will be as in Fig. 30-17, showing that the swinging of the weight is in phase with the disturbing motion of the support. Above the natural frequency, however, the string will appear crossed as in Fig. 30-18, showing that the motions at upper and lower ends are 180 deg out of phase.

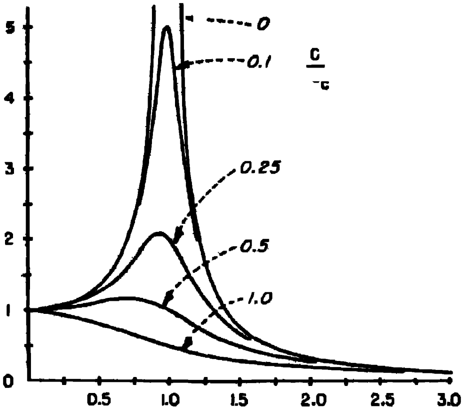

Fig. 30-15. Amplitudes of forced vibration with viscous damping.

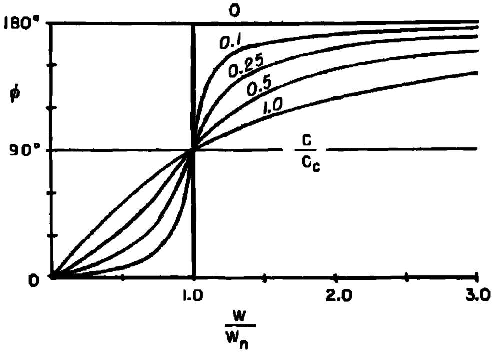

Fig. 30-16. Phase angles for forced vibration (see Fig. 30-14).

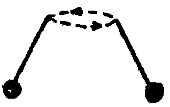

Fig. 30-17. Disturbing force and vibration in phase (below resonance).

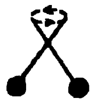

Fig. 30-18. Disturbing force and vibration 180 deg out of phase (above resonance).

The solution [Eqs. (27) and (28)] is the same for all numerical proportions of weight, damping, and spring rate; the motion is always vibratory, regardless of whether or not the damping exceeds the critical value.

RESILIENT SUSPENSION OF MOTORS AND MACHINES

Almost all power-driven devices generate vibration and noise, frequently to a disturbing extent. Reciprocating or unbalanced rotating parts create shaking forces. If impacts or explosions are involved in the working of the machine, these create noise and shock, both in the air and in the frame of the apparatus. Alternating-current electricity gives rise to magnetic hum. Gear teeth, pump and turbine blades, and electric commutators make sirenlike sounds of definite pitch, while ball or roller bearings give a confused clashing and rattling sound. The passage of water or other liquids, even at moderate speeds, is far from quiet.

If the machine is placed on a solid foundation in or near buildings, the disturbances are apt to be magnified and broadcast further. The usual types of building construction are very low in damping capacity; this is especially true of steel and reinforced concrete.

In many cases, the transmission of vibrations can be effectively prevented by interposing springs of suitable material and stiffness between the machine and its base. However, the installation must be properly designed, or matters will be worse instead of better.

If damping in the spring supports is neglected, all the necessary information can be obtained from Fig. 30-9 and Eq. (22). The maximum force applied to the machine is P_0. Let F_0 be the maximum force applied to the foundation. As the spring is the only element touching the foundation, F_0 will be equal to k times $x_{\max}$. From Eq. (22),

$$F_0 = kx_{\max} = P_0 \frac{1}{1 - (\omega^2/\omega_n^2)} \tag{29}$$

The ratio of F_0 to P_0 is known as the "transmissibility ratio" (TR), as it measures the effectiveness of the mounting in filtering out disturbances. From Eq. (29),

$$\text{TR} = \frac{F_0}{P_0} = \frac{1}{1 - (\omega^2/\omega_n^2)} \qquad \text{(Fig. 30-12)} \tag{30}$$

Figure 30-12 shows at once that spring mounting is beneficial only if the system is operating considerably above resonance, as it is only in this region that the transmissibility ratio is less than 1; anywhere below resonance, the spring mounting makes matters worse, as the force on the foundation is greater than that on the machine. Physically, the desired principle is to mount the machine in a soft or "floating" manner and thus allow the disturbing force to dissipate itself against the inertia of the machine instead of being transmitted into the supporting structure.

A question arises as to how low the transmissibility ratio should be made in order to secure good isolation. Hull[6,7,8] recommends that, for unbalance vibrations, ω/ω_n should be at least 3, while to secure satisfactory reduction of sound and noise frequencies, ω/ω_n must be 8 or more.

The spring rate necessary to produce a given transmissibility ratio is easily computed in a numerical case. It should be noted from Fig. 30-12 that, in the useful region (above resonance), the transmissibility ratio is a negative quantity, since the disturbing force and the motion are 180 deg out of phase. However, this negative sign is of no physical importance, and in the formulas below, transmissibility will be taken as a *positive* quantity. If the disturbance has a frequency of N cycles per min, $\omega = 2\pi N/60$. Substituting $\omega_n^2 = kg/W$ in Eq. (30) and solving for k gives

$$k = \frac{W}{g}\,\frac{4\pi^2N^2}{3{,}600[1 + (1/\text{TR})]} \tag{31}$$

the sign of the TR being changed. Combining the values of the numerical constants with $g = 386$ in. per sec per sec gives

$$k = 2.84 \times 10^{-5}\,\frac{WN^2}{1 + (1/\text{TR})} \tag{32}$$

EXAMPLE: The machinery of a refrigerator weighs 50 lb and contains a reciprocating compressor which operates at 400 rpm. Find the spring rate of the foundation for 10 per cent transmissibility ratio.

SOLUTION: $W = 50$ lb, $N = 400$ rpm, TR $= 0.10$. Substituting gives $k = 20.6$ lb per in. If the machine is mounted on four springs, each spring should have a rate of 5.2 lb per in. The center of gravity of the springs should be under the center of gravity of the suspended parts. Such an arrangement can vibrate in other ways besides simple vertical motion; these other modes are also analyzed by Hull.

EFFECT OF DAMPING IN SPRING SUSPENSIONS

If the foundation contains viscous damping as well as elasticity, as in Fig. 30-14, the expression for the transmissibility ratio under such conditions is[2]

$$\mathrm{TR} = \frac{\sqrt{1 + (2c\omega/c_c\omega_n)^2}}{\sqrt{[1 - (\omega^2/\omega_n^2)]^2 + (2c\omega/c_c\omega_n)^2}} \tag{33}$$

This function is plotted in Fig. 30-19. The results show that, in the useful range (well above resonance), damping is undesirable as it increases the force on the foundation. The damping does have the property of limiting the amplitude at resonance, an important point since the machine must pass through resonance every time it starts or stops. This is noticeable as a thumping noise in small electric refrigerators when the mechanism shuts down. In starting up, most machines pass through resonance so rapidly that large vibrations cannot build up. To provide protection against excessive motion at resonance, it is usually possible to provide bumpers which do not come into play at the regular running speed.

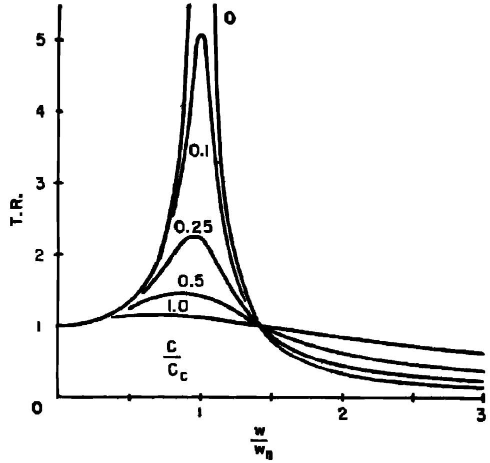

FIG. 30-19. Transmissibility ratio (spring mounting with damping).

In actual spring materials, such as rubber, the amount of damping is not usually known, nor is it of the simple viscous type. If a material is known to have considerable damping capacity, this can be counteracted by using a somewhat smaller value for the transmissibility ratio in applying Eq. (32) or (33).

SPRING MOUNTING OF DELICATE INSTRUMENTS FOR PROTECTION

It should be noted that the same "transmissibility factor" applies for transmission in either direction through the mounting. That is, if a disturbing force $P_0 \sin \omega t$ acts on the machine, the maximum dynamic force on the foundation will be $P_0 \times$ (TR). Also, if the support vibrates with a motion $a_0 \sin \omega t$ as in Fig. 30-12, the amplitude of vibration of the suspended mass will be $a_0 \times (TR)$. Both situations occur regularly in design work: in one case, a violent machine is spring-mounted to prevent radiation of shock and vibration in a structure or neighborhood; in the other, a delicate instrument is mounted on springs or rubber pads to protect it from vibration due to nearby machinery.

The lowest natural frequencies of building frames are likely to be in a range of 10 to 20 cps. An instrument mounting designed to filter out these frequencies will thus require a natural frequency of perhaps 3 to 6 cps. From Eq. (7), this means the instrument must deflect the mounting about half an inch. This may be too unstable for some applications. The building frame is also likely to carry high-frequency vibrations from shocks of various kinds. A somewhat stiffer mount may still be very beneficial against sound frequencies.

DESIGN OF VEHICLE SUSPENSIONS

Figure 30-19 can be applied directly to the design of vehicle springs and shock absorbers. Here the problem is to protect the body, load, and passengers from shocks due to waviness or bumps in the road.

The natural frequencies of modern cars are on the order of 1 cps or less. Thus the suspension will operate mostly above resonance, as very few bumps have a "wavelength" as great as the distance the car moves in 1 sec. (Railroad crossings are a notable exception.) In this region, any reduction of spring rate is beneficial, as it reduces ω_n and increases ω/ω_n, giving lower transmissibility. This is accomplished as far as possible by softer springs, softer tires, and better weight distribution.

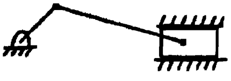
The shock absorbers are usually of the dashpot type. Figure 30-19 shows that, for best results, the damping constant must be variable. If the body is moving up and down at its natural frequency, the damping should be in the critical range so as to bring the body to rest quickly and smoothly. This action can be observed on automobiles by raising the bumper a few inches and dropping it. However, if the road is giving high-frequency bumps, as on cobblestones or "washboard" gravel, Fig. 30-19 shows that high damping makes the riding quality definitely worse. To take care of this, shock absorbers commonly have spring-loaded orifices. At body frequencies the damping is approximately critical, but at higher frequencies the increased oil pressure forces the orifices open, and the effective damping constant is reduced.

Many shock absorbers offer little resistance to closing up but employ some sort of check valve to exert a strong resistance to lengthening. So far as riding quality is concerned, this practice is of dubious value. It does not protect the body sufficiently against "striking bottom"; and on a continuously rough road, the result is merely to "rack the springs down" to a point where the average excess spring force compensates for the unbalanced action of the shock absorber. The purpose can perhaps be explained as protection for the usual flimsy shock absorber against bursting when the wheels are forced suddenly upward; but a stronger double-acting shock absorber would probably result in better spreading of the shock when the road profile requires rapid upward motion of the body.

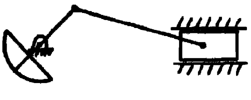
DESIGN DIFFICULTIES OF RESILIENT SUSPENSIONS FOR MACHINERY

There are a number of practical difficulties to be overcome in arriving at a successful resilient mounting. First is that of ignorance. Persons unfamiliar with vibration theory, when confronted with shaking machinery, are prone to conclude that a more massive foundation will dispose of the problem. Usually it will not, as it adds little damping capacity and does not lower the natural frequency enough to be helpful.

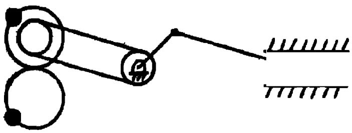
Sometimes it is possible to cure the trouble at the source by improving the balance or redesigning the troublesome mechanism. Single-cylinder engines or reciprocating pumps are frequent offenders in creating vibration. Such a mechanism cannot be inherently balanced (see Fig. 30-20). In the elementary form, the inertia force of the reciprocating mass creates a disturbance (Fig. 30-20*a*). If a counterweight of the correct amount is added to the opposite side of the crank, as in Fig. 30-20*b*, this will cancel the horizontal disturbing force (except for higher frequency components due to angularity of the connecting rod). However, there remains an unbalanced vertical force. In many machines, including steam locomotives, the practice is to make a compromise between these two extremes. A still better solution, however, is to add an auxiliary device known as a "Lanchester balancer."[9] As shown in Fig. 30-20c, this consists of two counterrotating shafts, geared together and geared in a positive manner to the crank. Each of the counterrotating shafts carries an unbalanced weight. These cancel each other in vertical motion, but they add together horizontally to oppose the inertia of the reciprocating parts. The cost of such devices is not great, they consume little power, and they frequently permit installing small steam engines in apartments, office buildings, hospitals etc., where vibration cannot be tolerated.



(a) No counterbalancing



(b) Rotating counterweight



(c) Lanchester balancer

Fig. 30-20. Methods of balancing single-cylinder mechanism.

If a machine is inherently disturbing, owing to nonuniform torque or some other condition, then spring mounting may be the only recourse. In designing such an installation, the most frequently encountered difficulties are as follows:

1. The design of suitable springs.
2. When designed for good isolation, the foundation may be too soft or "wobbly."
3. The machine may contain several disturbances at various frequencies. In designing to filter out vibrations of one frequency, care must be taken to avoid resonance with another frequency which may be present.
4. The machine on its mounting has more than 1 deg of freedom; *i.e.*, it can vibrate in different ways at different frequencies.
5. There may be conflicting rigidity requirements: soft for isolation, stiff for driving through gears or belts.
6. There may be several paths through which disturbances can escape from the machine, such as bearings, pipes, conduits, controls etc. All these should also be flexible enough to avoid fatigue failure from the vibrating motions of the spring-suspended machine.
7. Air-borne noise.

These will be discussed individually below.

1. Spring Design and Materials. Hull[8] gives a good summary of the problem of spring design and materials. A spring material should be easy to apply (as to existing machines); it must occupy little space, be low in cost, resistant to injury, have a long life, and have elastic properties which are constant and predictable. It should not "creep" or become hard with the passage of time. He lists as possible choices: (1) cork, felt, and gelatinous substances; (2) metals, especially steel; (3) rubber.

Type (1) materials tend to be expensive, uncertain in dynamic behavior, have high damping, flow plastically under load, and tend to lose elasticity with time. The latter is important, as it may be very inconvenient to remove a machine and a large foundation block in order to replace a resilient material underneath.

Metal springs can be successfully designed in many cases.[2,30] They do not deteriorate except for fatigue and corrosion, which are both preventable. However, they tend to be bulky; they are not easily applied to existing machines, and it is difficult to vary the stiffness in different directions.

Hull concludes that rubber is likely to prove the best spring material in many cases. It is cheap, takes little space, can be made in any size or shape (except that maximum thickness is limited), and is resistant to cutting or injury. It must be protected from sunlight, ozone, heat above 150°F or extreme cold, and oil.

Oxidation used to spoil rubber in 3 to 5 years. However, chemical additives have been found which greatly retard this process. Oxidation attacks only the surface layer of rubber to a depth of $\frac{1}{64}$ in. or so. Thus, rubber bands, gloves, raincoats, and bathing caps become useless in a few months or years; but thick pads will retain their elastic properties for many years.

Rubber was for a long time a proprietary or mystery material. Recently, however, much valuable information has been published on the elastic properties and other data important in spring design.[10] At present, it appears possible to design a rubber spring with as much assurance of life and elastic behavior as for metals.

At one time, application of rubber to mountings was held up by the difficulty of bonding it to metal. However, it was found that rubber would stick to brass. Steel fittings can be brass-plated and then joined to rubber with a bond strength which is many times the allowable working stress in the rubber itself. Likewise, in vulcanization with steam or electric heat, rubber could not be made more than about an inch thick, as rubber's heat conductivity is low, and the surface rubber would be damaged before the interior was properly "cooked." High-frequency electric heating has removed this restriction, as heat can now be generated uniformly throughout any thickness. As a result, application of rubber springs to streetcars and other large machines is becoming common.

2a. Conflicting Rigidity Requirements. It has been seen that, in order to secure good isolation, the natural frequency of the machine on its base must be low compared to the disturbing frequency. The low natural frequency implies soft springs. If the disturbing frequency is itself low, it may not be practical to design a sufficiently soft suspension.

Care should be taken to determine just what portions of a machine's noise or vibration are really objectionable. Everyone is familiar with the reduction of noise from a typewriter when it is placed on rubber feet or a felt pad. In such a case, the natural frequency of the typewriter in vertical motion is much *higher* than the frequency of striking the keys. Theory indicates that the mounting should then make matters worse, but experience shows the opposite. The explanation is that it is not the fundamental frequency of key striking which creates objectionable noise. When a key is struck, the frame and other parts of the machine start to vibrate at their own natural frequencies, which may be very high. These latter are easily filtered out by the padding; hence a noticeable reduction in noise is attained. The mounting theory for impact machines is discussed below.

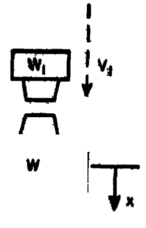


FIG. 30-21. Dynamic parts of drop-forging hammer.

2b. Elastic Mounting of Drop-forging Hammers. In the past, drop-forging plants have frequently been the cause of complaints and lawsuits because of the noise and heavy vibration transmitted to nearby buildings. In addition, in many cases, the hammer causes rapid deterioration of its own foundation, necessitating frequent and expensive repairs. It is easy to show that these unpleasant characteristics can be mitigated by two simple steps: (1) mount the machine on springs; (2) if necessary, add more mass to the anvil.

Figure 30-21 shows the three dynamic parts of the forging hammer: the striking mass W_1, the anvil W, and the elasticity k of the foundation (even a "rigid" foundation has some springiness).

Suppose the hammer, weighing W_1 lb, falls and strikes the work on the anvil with a velocity V_1 in. per sec. Usually, the hammer will not rebound, as its energy is used up in plastically deforming the metal being worked. If the hammer and anvil remain together, they will start downward with a common velocity V in./sec, which can be found from the well-known principle of the conservation of momentum:

$$W_1V_1 + W(O) = (W_1 + W)V \tag{34}$$

(It is assumed that this common velocity is reached before the anvil moves appreciably.)

The maximum amount x_0 by which the spring k will be compressed can now be computed by conservation of energy. As W and W_1 begin their motion, they have kinetic energy $E_k = \frac{1}{2}[(W + W_1)/g]V^2$. Since $V = W_1V_1/(W + W_1)$ from Eq. (34), $E_k = \frac{1}{2}[W_1^2/(W + W_1)g]V_1^2$. When all this kinetic energy of motion has been converted into potential energy E_p in the spring, the weights will be stopped. Since $E_p = \frac{1}{2}kx_0^2$, conservation of energy requires that

$$\frac{1}{2}kx_0^2 = \frac{1}{2}\frac{W_1^2}{(W + W_1)g}V_1^2 \qquad (35)$$

Solving, the maximum compression x_0 of the spring is

$$x_0 = W_1V_1\sqrt{1/[k(W + W_1)g]} \qquad (36)$$

The maximum dynamic force F_0 transmitted to the foundation is

$$F_0 = kx_0 = W_1V_1\sqrt{k/[(W + W_1)g]} \qquad (37)$$

The results of any change in the system can be easily seen from Eqs. (36) and (37). W_1V_1 represents the momentum of the hammer as it strikes. This probably should not be reduced if the hammer is to continue to do its work; such a question is beyond the present scope. W and k are the quantities which can be varied. By simultaneously increasing W and reducing k, the transmitted force F_0 can be reduced, while the action of the hammer will remain as effective as before. That is, if the product $(W + W_1)k$ is kept constant, Eq. (36) shows that the hammer-stopping distance will not change; hence the available inertia force and power to work the metal will remain the same. However, it can be seen in Eq. (37) that, if k is reduced and W increased, both these changes will reduce the transmitted disturbance F_0. As W_1 is only a small fraction of W in actual hammers, it can be concluded in any given case that, if the anvil weight W is doubled while the foundation stiffness k is cut in half, the disturbing force F_0 will be reduced to half its previous value, etc. If the stopping distance x_0 is permitted to increase, a still further reduction in F_0 can be had.

If the above principles are observed in designing and installing forging hammers, it appears quite practical to prevent the hammer from shaking up its neighborhood without reducing the effectiveness of the machine itself. Both the larger anvil and the softer springs may increase the cost of the installation, but not out of reason.

In forging slanted and unsymmetrical articles such as propeller blades, there is frequently a tendency for the hammer to move sidewise off its base. It may be necessary to provide horizontal springs and abutments to control this effect.

3. Frequency Disturbances. [See (3), page 1810.]

4. Many Types of Motion Possible. Thus far, the discussion has been confined to vibrations in which the mass moved back and forth in one direction only without rotations. While such a system is adequate to explain certain phenomena of vibration, such as resonance and isolation, there are many actual systems whose motions are more complicated. The "number of degrees of freedom" of a system is the number of independently variable displacements which must be given in order to specify the positions of the moving elements.

In general, a rigid body supported on springs has six degrees of freedom; it can move in three directions, and it can rotate about each of these axes. The number of degrees of freedom is equal to the number of natural frequencies at which the system can vibrate.[1,2]

In most cases, the calculation of the natural frequencies is a problem of considerable difficulty, as the motions are "impure," involving simultaneous translations and rotations. Hull[6] gives formulas for the six natural frequencies of a symmetrical mechanism mounted on a rectangular plate supported by springs at the corners. Crede and Walsh[11] have designed a vibrating-table installation in which all six of the natural frequencies are the same. The general methods for attacking such problems are discussed on page 1829.

5. Maintaining Alignment of Power Drives. In the case of motors, it occurs frequently that the torque is nonuniform or pulsating, although the rotational parts are in balance and do not generate lateral vibration. This is true of single-phase electric motors and also automobile engines. Various mountings have been designed which filter out the torsional vibration while maintaining lateral rigidity so that the motor remains in alignment and can drive its load.[2] Small electric motors for washing machines, refrigerators, etc., are frequently mounted in a U-shaped cradle with rubber rings around the bearings at each end. The soft rings filter out torsional impulses but are quite rigid against lateral deflection. Similar arrangements for mounting automobile engines on rubber pads are in nearly universal use.

6. Alternative Paths for Vibration Transmission. If power-driven machinery is to be effectively isolated by resilient mountings, all attachments to such machinery must be made sufficiently flexible. Bearings can be mounted in rubber. Pipes and conduits can be provided with spirals, horseshoe bends, etc., if necessary, to decrease their rigidity. Control levers can be made flexible, passed through rubber grommets, etc.

7. Noise Measurement and Reduction. Engineering investigations of noise were formerly hampered by the lack of suitable methods of impersonal measurement. However, there are now several companies marketing sound meters, and the American Standards Association has established standards for their performance and calibration.[12] Of the available instruments, the "sound-level meters" and "sound analyzers" of the General Radio Co. are probably the best known and most widely used.[13]

As a result of fundamental research by telephone engineers, sounds are now measured on the "decibel scale." This is a logarithmic scale measuring sound pressures or powers above a standard reference level. The human ear, like the other senses, has a somewhat logarithmic sensitivity, described by the well-known Weber-Fechner law of sensation. This states that, if F is the quantity of something being sensed, such as amount of weight lifted or loudness of a sound heard, and ΔF is the least detectable change in the quantity being sensed, then $\Delta F/F$ = constant. Thus if a man can detect a 5-lb change in 100 lb of weight, he should also detect $\frac{1}{20}$-lb change in a 1-lb weight. If the man in lifting any weight has a "sensation of weight" S by which he can judge whether the amount is 2, 20, 200 lb, etc., then

$$\Delta S = \Delta F/F \qquad \text{or} \qquad S - S_0 = \log (F/F_0) \tag{38}$$

If F_0 is a "threshold" or minimum quantity which can be detected, then $S_0 = 0$. Because of the logarithmic characteristic, a tremendous range of intensities can be safely experienced. All the human senses operate roughly in this way, although precise experiments will show distinct deviations from the simple logarithmic law.

A "pure tone" is a sound of definite pitch due to constant-frequency sinusoidal oscillations of pressure in the air. If E is the amplitude of pressure variation in such a tone, then the loudness of the tone on the decibel scale is given by

$$\text{db} = 20 \log_{10} (E/E_0) \tag{39}$$

where E_0 is a standard reference level of 0.0002 dynes per sq cm at 1,000 cps.

Within the audible frequency range, the amount of power P necessary to maintain a pure tone will be very nearly proportional to the square of the pressure. If Eq. (39) is written in terms of power instead of pressure,

$$\text{db} = 10 \log_{10} (P/P_0) \tag{40}$$

where P_0 corresponding to E_0 = 0.0002 dynes per sq cm is about 10^{-16} watts per sq cm. A "sound-level meter" is thus a device for measuring the power of sounds striking its microphone and giving readings in decibels.

A sound of 130 db will cause physical pain in the ear, and continued exposure to 100 db or more will eventually cause deafness. Three decibels is about the smallest change in a given sound which is detectable. At the other end of the scale, the threshold of hearing for average persons is around 20 db. A completely quiet location is almost nonexistent; there are few places where the average noise level is below 40 db. Table 30-1 gives representative readings on sounds commonly experienced:

Table 30-1. Loudness of Common Sounds, Decibels

Circumstances	*Decibels*
Airplane-motor test cell	140
Pneumatic rock drill, airplane motor at 20 ft	130
Auto horn	120
Punch press, boiler factory (riveting)	110
Platform of elevated or subway station, newsboy shouting	100
Heavy street traffic, noisy factory, airplane cabin	90
Noisy office, loud radio, noisy restaurant	80
Average factory, typewriting office, traffic on boulevard	70
Normal conversation, "noiseless" typewriter, inside railroad train	60
Inside quiet automobile	50
Quiet home	40
Broadcasting studio	30
Country road, whisper in quiet room	20

Men and machinery can create a great diversity of noise problems, but there are certain fundamental situations of frequent occurrence. Among these are

1. Two similar machines running at once give a sound level only 3 db more than one machine running alone. This is obtained from Eq. (40) since

$$10 \log_{10} (2P/P_0) - 10 \log_{10} (P/P_0) = 10 \log_{10} 2 = 3 \text{ db}$$

Thus if a machine contains two sources of noise of about equal power, it does little good to reduce only one of them.

2. Two similar machines placed in proximity will create "wave patterns" of noise. If identical pure tones are generated at two points of a room with completely sound-absorbing walls, the sound pressure at a series of neighboring locations may vary from double (+6 db) to nothing. In a more practical situation, machines do not generate pure tones, and there is a certain level of background noise. However, sound readings in the neighborhood of two similar machines will show fluctuations with position. Likewise, a single machine in a room with hard walls will create wave patterns by reflection. It is always advisable to measure sound at several positions and take an average if the wave-pattern condition exists.

3. Human psychology is frequently important. People will tolerate a great deal of noise if they feel the cause is useful and necessary. At the same time, they will complain against a very moderate noise if created by persons whom they dislike for any reason.

4. Whether a certain noise is important depends on its relation to other background noises. A sound whose individual power is more than 10 db below the general level will probably be inaudible, although it might sound very loud in a quiet place.

A valuable paper by Abbott[14] discusses 12 cases in which a great variety of machinery was successfully treated to reduce noise. Both theory and experimental methods are clearly described. The following general principles may be mentioned:

1. Frequently, noise vibrations do not originate in the component which radiates them to the air. If flexible parts or "mechanical filters" can be interposed between a motor and a sheet-metal housing, for example, the noise level can be greatly reduced.

2. If one part of a machine excites resonant vibration in another part, a slight change in the mass or stiffness of the latter is beneficial. If this situation is suspected, it can be studied by varying the speed of the driving motor by some means.

3. In either (1) or (2), if more than one path of vibration transmission exists, it will probably do little good to cut down only one channel (see 1 above).

4. If a machine is complicated and emits a variety of sounds, it may be necessary to analyze the total noise into its components at various frequencies. In this way, noise of a certain frequency can usually be traced to the part causing it. Likewise, it may be helpful to study instantaneous noise vs. rotation of the shaft of the machine, using an oscillograph.

5. The "noise spectrum" of a machine part may be altered by the structure to which it is later attached. In one case, a rear axle, when tested on a production stand, had a strong fundamental-frequency noise and a weak second harmonic. When

installed in an automobile, however, the fundamental was suppressed, and the harmonic became predominant. In acceptance testing of production axles, the second harmonic was therefore of paramount importance, but it could not even be heard on the original testing stand.

SYSTEMS WITH TWO DEGREES OF FREEDOM

It has already been seen that a system with one degree of freedom may consist of a weight suspended on a spring (Fig. 30-1) or any kind of rigid pendulum (Fig. 30-7). Thus the vibratory motion may be linear or angular; but with 1 deg of freedom there can be only one natural frequency at which vibrations occur.

Figure 30-22 shows one of the simplest cases in which there are two degrees of freedom. It is assumed that the masses are constrained to move only in a vertical direction. Since the position of both masses must be known in order to specify the configuration of the system at a given instant, there are two degrees of freedom. There will also be two natural frequencies of vibration: a slower mode in which the masses move up and down in unison (though the amplitudes of the masses may be different) and a faster mode in which the masses always move in opposite directions. This conclusion, based on experience or experiment, can also be worked out mathematically. Figures 30-23a and 30-23b show free-body diagrams of the masses, from which the following equations are obtained:

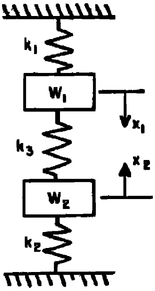

FIG. 30-22. Two vibrating systems coupled together.

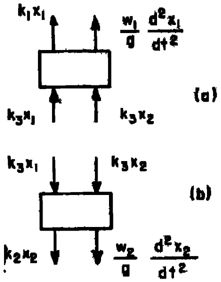

FIG. 30-23. Free-body diagrams for Fig. 30-22.

$$\frac{W_1}{g}\frac{d^2x}{dt^2} + (k_1 + k_3)x_1 + k_3x_2 = 0 \tag{41}$$

$$\frac{W_2}{g}\frac{d^2x}{dt^2} + (k_2 + k_3)x_2 + k_3x_1 = 0 \tag{42}$$

(As usual, the weights have been eliminated by measuring x_1 and x_2 from the equilibrium positions.) Introduce the symbols

$$s_1{}^2 = \frac{(k_1 + k_3)g}{W_1} \qquad s_2{}^2 = \frac{(k_2 + k_3)g}{W_2} \qquad s_3{}^2 = \frac{k_3 g}{\sqrt{W_1W_2}} \tag{43}$$

Equations like (41) and (42) are readily solved by assuming

$$\left.\begin{aligned} x_1 &= a_1 \sin \omega t \\ x_2 &= a_2 \sin \omega t \end{aligned}\right\} \tag{44}$$

and substituting. It is found that a_1, a_2, and ω can always be adjusted to satisfy the equations of motion, and there will always be two such solutions. The substitution gives

$$\left.\begin{aligned} a_1(s_1{}^2 - \omega^2) + \frac{k_3 g}{W_1}a_2 &= 0 \\ a_2(s_2{}^2 - \omega^2) + \frac{k_1 g}{W_2}a_1 &= 0 \end{aligned}\right\} \tag{45}$$

If Eqs. (45) are regarded as simultaneous equations in a_1 and a_2, there is no constant term in either equation. Hence, a_1 and a_2 can have values different from zero only if each equation gives the same value for the ratio a_1/a_2. This furnishes a third relation from which the unknown ω can be found. Thus

$$\frac{a_1}{a_2} = \frac{-k_3g}{W_1(s_1^2 - \omega^2)} = \frac{-W_2(s_2^2 - \omega^2)}{k_3g} \tag{46}$$

Using the second and third parts and clearing fractions gives the following quadratic for ω^2:

$$(s_1^2 - \omega^2)(s_2^2 - \omega^2) = \frac{k_3^2g^2}{W_1W_2} = s_3^4$$

or

$$\omega^4 - (s_1^2 + s_2^2)\omega^2 + s_1^2s_2^2 - s_3^4 = 0 \tag{47}$$

Hence

$$\omega^2 = s_1^2 + s_2^2 \pm \frac{\sqrt{(s_1^2 + s_2^2)^2 - 4s_1^2s_2^2 + 4s_3^4}}{2} \tag{48}$$

The quantity under the radical will always be positive, since it can be written as,

$$(s_1^2 - s_2^2)^2 + 4s_3^4 \tag{49}$$

which is a sum of squares. Also, the value of the radical is always less than $s_1^2 + s_2^2$, since the quantity underneath is

$$(s_1^2 + s_2^2)^2 - 4(s_1^2s_2^2 - s_3^4) \qquad \text{and} \qquad s_1^2s_2^2 - s_3^4 = \frac{(k_1k_2 + k_2k_3 + k_3k_1)g^2}{W_1W_2} \tag{50}$$

which cannot be negative. Thus, for any real system as in Fig. 30-22, Eq. (48) will always give two positive but different values for ω^2. When one of these values is selected, Eq. (46) determines the value of a_1/a_2 associated with this frequency of vibration.

EXAMPLES: 1. The simplest case occurs when $W_1 = W_2 = W$ and $k_1 = k_2 = k$. If ω_a^2 and ω_b^2 represent the two natural frequencies, it is found that

$$\omega_a^2 = kg/W$$

where $a_1/a_2 = -1$

and $\omega_b^2 = [(k + 2k_3)g]/W$

where $a_1/a_2 = 1$

The a-type vibration can be recognized as one in which the masses move up and down in unison through the same amplitude, with a frequency $f_a = \omega_a/2\pi$ cps per sec. Since the coupling spring k_3 does not change its length during such a motion, it is like a rigid connection and has no effect on the frequency. The b-type motion is one in which the masses move in opposite directions with equal amplitude at a frequency $f_b = \omega_b/2\pi$. In such a motion, the center point of k_3 remains stationary. If this is regarded as a fixed point, the stiffness of one-half of k_3 is $2k_3$, which explains the result for f_b since each mass is vibrating on springs equivalent to $k + 2k_3$.

2. As a general numerical example, let $W_1 = 30$ lb, $W_2 = 50$ lb, $k_1 = 20$, $k_2 = 30$, $k_3 = 40$ lb per in. Substituting in the equations, it is found that the lower frequency is 2.93 cps, with $a_1/a_2 = -1.137$, while the faster frequency is 7.10 cps, with $a_1/a_2 = 0.431$.

3. A case of some practical importance occurs with k_1 and k_2 zero. This can be visualized as a pair of railroad cars on a track, connected by a spring, friction being neglected. Solving the equations, it is found that one frequency is zero (corresponding to motion of the system along the track at uniform speed, a "vibration" of zero frequency), while the other is

$$f = (1/2\pi)\sqrt{[k_3g(W_1 + W_2)]/W_1W_2} \tag{51}$$

It is also found that, for the vibrating mode, $a_1/a_2 = W_2/W_1$, or $W_1a_1 = W_2a_2$, showing that the center of gravity of the system does not move during a vibration, since no external forces are acting. The position of the "node" or stationary point of the spring can be determined from this relation; the node divides the system into two parts, each of which must have the same natural frequency.

4. In Example 1, the symmetrical case, an interesting type of behavior occurs when the coupling spring k_3 is made very weak compared to the others. This makes the two natural frequencies fall very close together. Figure 30-24 shows a pair of equal pendulums connected by a weak spring, giving a system in which one natural frequency (with the pendulums moving in phase) is slightly less than the other frequency in which the motions are opposed. This occurs because in one type of motion the coupling spring is not stretched,

while in the other it is. If the system is disturbed by moving one pendulum aside and releasing it, the first pendulum will swing with a slowly decreasing amplitude until it comes to rest. During the same time, the second pendulum gradually builds up a vibration equally large. A typical record is shown in Fig. 30-25. From this point on, the procedure continues cyclically, with the motion transferring from one pendulum to the other and back again, until friction brings the system to rest. A vibration with variable amplitudes of this kind is known as "beating." It is a familiar effect in music when two instruments of slightly different pitch are sounded together. As one vibration gradually changes phase with respect to the other, the sound intensity varies from double to nothing. The "beat frequency" is the difference in the two primary frequencies: thus, when tones of 256 and 258 cps are sounded, a beat frequency of 2 per sec will occur.

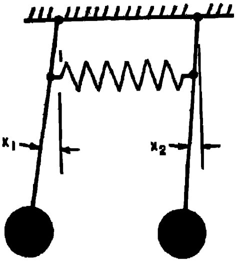

FIG. 30-24. System with two nearly equal natural frequencies (illustrates "beating").

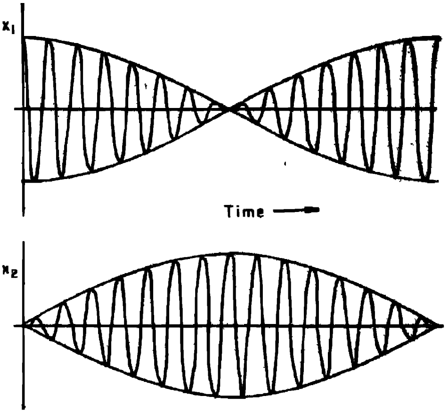

FIG. 30-25. "Beating" motions possible with Fig. 30-24.

Such motions can be demonstrated mathematically by using the complete solution of the differential equations. This is

$$\left.\begin{aligned} x_1 &= A_1 \cos \omega_1 t + B_1 \sin \omega_1 t + A_2 \cos \omega_2 t + B_2 \sin \omega_2 t \\ x_2 &= A_1 \cos \omega_1 t - B_1 \sin \omega_1 t + A_2 \cos \omega_2 t + B_2 \sin \omega_2 t \end{aligned}\right\} \tag{52}$$

Suppose that when $t = 0$, $x_1 = x_0$, $x_2 = 0$, and the velocities are zero. The constants are found to be

$$A_1 = A_2 = x_0/2 \qquad B_1 = B_2 = 0$$

giving

$$\begin{aligned} x_1 &= x_0/2(\cos \omega_1 t + \cos \omega_2 t) \\ x_2 &= x_0/2(-\cos \omega_1 t + \cos \omega_2 t) \end{aligned} \tag{53}$$

By trigonometric identities, these become

$$\left.\begin{aligned} x_1 &= x_0 \cos\left(\frac{\omega_1 + \omega_2}{2} t\right) \cos\left(\frac{\omega_1 - \omega_2}{2} t\right) \\ x_2 &= x_0 \sin\left(\frac{\omega_1 + \omega_2}{2} t\right) \sin\left(\frac{\omega_1 - \omega_2}{2} t\right) \end{aligned}\right\} \tag{54}$$

Curves like Fig. 30-25 can be obtained from these equations.

5. Figure 30-26 shows a side view of the suspended parts of an automobile. Considering only motions parallel to the plane of the paper, the system has two degrees of freedom, as it can move vertically and also rotate about a transverse axis. The natural modes and frequencies can be found by the same procedure as used above. Let x be the downward motion of the center of gravity and ϕ be the counterclockwise rotation. Then, as shown in Fig. 30-27, the compression of the front and rear springs will be $x + a\phi$ and $x - b\phi$, respectively. It is necessary to know the moment of inertia I of the body about a transverse axis through G in order to write the force equations. Using the free-body diagram in Fig. 30-28, two equations are obtained, one for summation of vertical forces, the other for moments about G. These are

$$\frac{W}{g}\frac{d^2x}{dt^2} + k_1(x + a\phi) + k_2(x - b\phi) = 0 \tag{55}$$

$$I\frac{d^2\phi}{dt^2} + k_1a(x + a\phi) - k_2b(x - b\phi) = 0$$

Assuming $x = x_0 \sin \omega t \quad \text{and} \quad \phi = \phi_0 \sin \omega t$ (56)

gives
$$\frac{-\phi_0}{x_0} = \frac{k_1 + k_2 - (W/g)\omega^2}{k_1a - k_2b} = \frac{k_1a - k_2b}{k_1a^2 + k_2b^2 - I\omega^2} \tag{57}$$

In a numerical case, the two natural frequencies are easily found from the quadratic equation for ω^2. Each of these in turn determines the ratio of x_0/ϕ_0, which gives the distance d to the apparent center of rotation for that mode, as shown in Fig. 30-29.

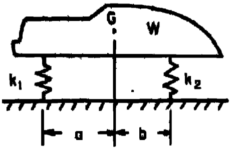

Fig. 30-26. Side view of dynamic parts of automobile suspension.

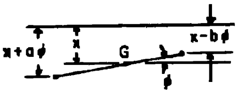

Fig. 30-27. Displacement and pitching rotation coordinates for Fig. 30-26.

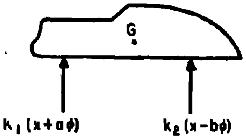

Fig. 30-28. Free-body diagram for Fig. 30-26.

It is possible to adjust the locations of the springs in such a way that in one mode of vibration, the system pivots about the front spring, while in the other it pivots about the rear spring. Let k be the radius of gyration of the body, defined by $I = Wk^2/g$. It can be shown that the above condition will occur if $k^2 = ab$. That is, if $k^2 = ab$, the vertical motion at one spring is independent of vertical motion at the other spring. This may be shown as follows: if a vibration mode is to exist with no motion at the front spring, then it is necessary that

$$x_0 + a\phi_0 = 0 \qquad \text{or} \qquad -\phi_0/x_0 = -1/a$$

Substituting this in Eq. (57), it is found that

$$\omega^2 = [k_2(a + b)g]/Wa = [k_2b(a + b)]/I \tag{58}$$

from which $k^2 = ab$. If we begin by assuming no motion at the rear spring, then

$$x_0 - b\phi_0 = 0$$

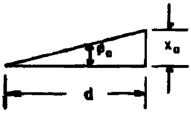

Fig. 30-29. Locating apparent centers of rotation for automobile-body motions (see Fig. 30-26).

When this is substituted, it also gives $k^2 = ab$.

The result is independent of the spring rates k_1 and k_2, although these control the frequencies in their respective modes. The condition may be described by saying that each spring is located at the center of percussion of the other spring. This is thought to be the best arrangement for riding comfort, since, when the front wheels strike a bump, only the front springs are compressed; and the same is true for the rear. If the condition is not satisfied, then a bump at the front wheels may compress both front and rear springs. If the rear springs are already compressed when the rear wheels strike the same bump, the probability of bottoming and general roughness is increased.

The above analysis was not available until 1923 and was not applied until several years thereafter. In the early days, it was thought that a long wheel base promoted riding comfort, hence the axles were placed at the extreme front and rear of the chassis. In such an arrangement, ab will be much greater than k^2, and a very rough ride results. In modern cars, the axles have been moved toward the center of the car. The front axle is now partly under the engine, while the rear axle has moved forward under the rear seat. Heavy bumpers, trunks, grills, etc., are used at both ends of the car in the attempt to get as much mass as possible beyond the axles. The result more nearly approaches the desired $k^2 = ab$ condition, but it is not possible to reach it completely without having the axles so far under the car that steering control at high speeds is impaired, with the added hazard of having the projecting portion of the car strike the ground when moving over uneven pavement such as steep driveway entrances, etc. Thus the final design is a compromise, although soft springs and tires are also used to lower the natural frequencies and promote riding comfort.

DYNAMIC VIBRATION ABSORBER

Figure 30-30 shows another important case having two degrees of freedom. W_1 and k_1 indicate a piece of machinery or structure subject to a disturbing force $P_0 \sin \omega t$. W_2 and k_2 represent a "damper" which will entirely prevent any forced vibration of W_1, provided the damper is tuned so that $k_2g/W_2 = \omega^2$. This can be shown as follows: considering each mass as a free body and summing vertical forces gives the two equations

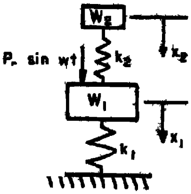

FIG. 30-30. Use of Dynamic Vibration Absorber to prevent vibration.

$$\frac{W_1}{g}\frac{d^2x_1}{dt^2} + (k_1 + k_2)x_1 - k_2x_2 = P_0 \sin \omega t \tag{59}$$

$$\frac{W_2}{g}\frac{d^2x_2}{dt^2} + k_2x_2 - k_2x_1 = 0 \tag{60}$$

The system is, of course, capable of executing free vibrations. There are two natural frequencies, which can be computed as shown previously. However, any such free vibrations in an actual system would soon be damped out by friction, so that only the forced vibrations at a frequency $\omega/2\pi$ are important. Assuming $x_1 = a_1 \sin \omega t$, and $x_2 = a_2 \sin \omega t$ and substituting gives two simultaneous equations for a_1 and a_2:

$$[k_1 + k_2 - (W_1/g)\omega^2]a_1 - k_2a_2 = P_0 \tag{61}$$

$$-k_2a_1 + [k_2 - (W_2/g)\omega^2]a_2 = 0 \tag{62}$$

For simplicity, let $k_1g/W_1 = \Omega_1^2$ and $k_2g/W_2 = \Omega_2^2$ (63)

The results are found to be

$$a_1 = \frac{P_0}{k_1}\,\frac{1 - (\omega^2/\Omega_2^2)}{\left(1 - \frac{\omega^2}{\Omega_2^2}\right)\left(1 + \frac{k_2}{k_1} - \frac{\omega^2}{\Omega_1^2}\right) - \frac{k_2}{k_1}} \tag{64}$$

$$a_2 = \frac{P_0}{k_1}\,\frac{1}{\left(1 - \frac{\omega^2}{\Omega_2^2}\right)\left(1 + \frac{k_2}{k_1} - \frac{\omega^2}{\Omega_1^2}\right) - \frac{k_2}{k_1}} \tag{65}$$

Equation (64) shows that, if $k_2g/W_2 = \Omega_2^2 = \omega^2$, then a_1 will be zero, thus establishing the condition stated at the beginning. Equation (65) shows that a_2 then equals $-P_0/k_2$, or $-k_2a_2 = P_0$. This shows the physical behavior of the tuned damper; it vibrates at exactly the right phase and amplitude so that the variable force in k_2 neutralizes the disturbing force, thus eliminating any vibration of the main mass W_1.

Such a damper is, in many cases, ideally suited for preventing vibration. Large vibrations of W_1 will not build up unless the disturbing frequency ω is close to the natural frequency $\Omega_1 = \sqrt{k_1g/W_1}$. In such a case, even a small disturbing force $P_0 \sin \omega t$ can build up a large vibration by resonance. Hence, if only a small disturbing force is involved, the vibration can be cured with a damper mass which is a very small fraction of the main weight W_1. Since the disturbing force is opposed by inertia rather than friction, no energy is converted by the damper. Thus the efficiency of the original machine is not affected, nor is there a problem of maintaining a correct frictional adjustment in the damper.

Whether such a damper is practical in a given case depends on the magnitude and frequency of the disturbing force. The damper spring k_2 must be able to stand up indefinitely when subjected to an alternating load of $\pm P_0$. Also, when $a_1 = 0$, Eqs. (63) and (65) show that $P_0 = k_2a_2 = W_2\omega^2a_2/g$. This determines the necessary size of damper weight W_2 for a specific application, as a_2 will usually be limited by the design of the spring. If P_0 is small and the disturbing frequency $\omega/2\pi$ is high, a small damper weight will suffice. As ω is reduced, however, the required damper eventually reaches cumbersome and impractical proportions.

Dampers of this type have been successfully applied in such diverse situations as electric hair clippers[16] and bending vibrations of the hull structure of a merchant ship.[17]

If the disturbing frequency $\omega/2\pi$ is variable, the damper may be worse than useless, as it creates two natural frequencies instead of one. Large vibrations will then build up if the disturbing frequency coincides with either of these natural frequencies. In one case, the masses vibrate in phase; in the other, their motions are opposed.

In the hair clipper, the disturbance was due to constant-frequency (60-cycle) electromagnetic impulses. In the motorship, the vibration was caused by impulses from the propeller blades. The engine speed varied over a certain range. However, since the ship would usually run for hours or days at one speed, it was practical to adjust the damper for the speed being used by running water to the proper level in a tank which was part of the damper mass.

By an ingenious extension of the dynamic-absorber principle, it has been applied to the reduction of torsional vibration in airplane engines.[18] The disturbing frequency varies with the running speed of the engine. The damper is made in the form of a "torsional pendulum" whose "spring" is provided by centrifugal forces. As these vary with the square of the speed, a relation like Eq. (63) can be made to hold at all speeds, thus removing the constant-frequency limitation.

Another possibility is to introduce dry or viscous friction in the damper in addition to spring action. Such a device will no longer prevent vibration entirely, but it holds it to a safe value even in passing through resonance. The theory has been completely worked out,[2,19] and some successful applications have been made.[20]

SYSTEMS OF SEVERAL DEGREES OF FREEDOM

Previously, systems with one or two degrees of freedom have been considered. It was seen that the number of natural frequencies equals the number of degrees of freedom and that for each frequency the amplitudes of vibration of the masses are in a fixed ratio with each other. All amplitudes may be increased or decreased proportionally, depending on initial conditions, but the relative amplitudes for each natural frequency are fixed by whatever mass and stiffness arrangement exists in the system.

FIG. 30-31. Vibrating system with many uniform parts (the "string-of-beads" problem).

When more than two degrees of freedom must be considered, the general results are the same as above, but the labor of computing them increases rapidly with the complexity of the system, and more advanced mathematical methods are required. A completely general case of six degrees of freedom, with nonuniform masses and with each mass elastically connected to most of the other masses, may require 12 to 15 hr of computing if all six of the natural modes and frequencies must be found.

Systems with Uniform Parts. Many problems of practical importance have especially simple structural forms so that shorter methods can be used. In some cases, formula solutions exist for the natural frequencies and proportional amplitudes. Figure 30-31 shows the classical "string-of-beads" problem, first solved by Lagrange ("Mecanique Analytique," 1787). A weightless string is stretched with a tension T. It carries uniform "beads" of mass m at equal intervals L along the string. The problem is to find the natural frequencies and proportional amplitudes for small lateral vibrations. If there are n beads, it can be shown by the so-called "calculus of finite differences"[21] that the n natural frequencies are given by

$$f_s = \frac{1}{\pi}\sqrt{\frac{T}{mL}}\sin\left[\frac{s(180°)}{2(n+1)}\right] \tag{66}$$

where $s = 1, 2, \ldots n$. If the masses are numbered from left to right, the mass number being r, the proportional amplitudes are

$$a_{rs} = C_s \sin\left[\frac{sr(180°)}{n+1}\right] \tag{67}$$

where C_s is an arbitrary constant, and s and r each range independently from 1 to n. That is, if $s = 3$, the third natural frequency is being considered; and if r is given values from 1 to n in succession, the relative amplitudes of the masses are found.

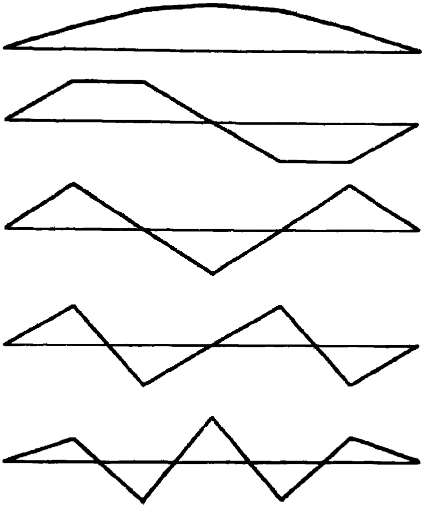

FIG. 30-32. The five possible types of free vibration in one plane for Fig. 30-31.

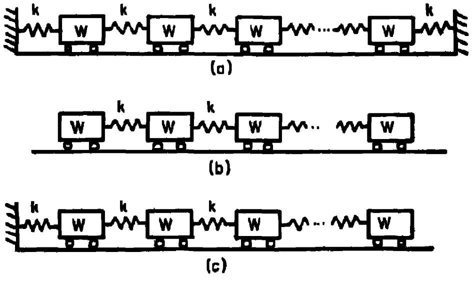

FIG. 30-33. Analysis of longitudinal vibrations in trains of cars.

EXAMPLE: Let $n = 5$, $T = 100$ lb, $L = 20$ in., and the weight of each mass $= 0.2$ lb. Then $m = W/g = 0.2/386$. The natural frequencies are found to be 8.11, 15.7, 22.2, 27.2, and 30.2 cps. The proportional amplitudes are shown in Fig. 30-32.

Figures 30-33*a*, *b*, and *c* show three similar problems. In each case, n cars of weight W rest on a frictionless track and are connected by frictionless springs whose rate is k lb per in. Horizontal vibrations in the train are to be considered, with varying end conditions. The general procedure is well explained by Karman and Biot.[21] The following results can be obtained:

1. When both ends are fixed to immovable supports by springs k, there are n natural frequencies, given by

$$f_s = \frac{1}{\pi}\sqrt{\frac{kg}{W}}\sin\left[\frac{s(180^\circ)}{2(n+1)}\right] \quad \text{where } s = 1, 2, \ldots, n \tag{68}$$

The proportional amplitudes are given by Eq. (67).

2. When both ends are free, there are only $n - 1$ vibration frequencies, as the entire train can move at uniform speed, a "vibration" of zero frequency.

$$f_s = \frac{1}{\pi}\sqrt{\frac{kg}{W}}\sin\left[\frac{s(180^\circ)}{2n}\right] \tag{69}$$

$$a_{rs} = C_s \cos\left[\frac{s(2r-1)(180^\circ)}{2n}\right] \tag{70}$$

where $s = 1, 2, \ldots, n - 1$, and $r = 1, 2, \ldots, n$.

3. When one end is free, and one end is fastened to fixed support by spring k,

$$f_s = \frac{1}{\pi}\sqrt{\frac{kg}{W}}\sin\left[\frac{(2s-1)(180^\circ)}{2(2n+1)}\right] \tag{71}$$

$$a_{rs} = C_s \sin\left[\frac{(2s-1)r(180^\circ)}{(2n+1)}\right] \tag{72}$$

where $s = 1, 2, \ldots, n$, and $r = 1, 2, \ldots, n$.

If the mass weights or spring constants, or both, are nonuniform, the method of finite differences can no longer be applied, except for the case where the nonuniformities are confined to one unit at each end of the train.

Longitudinal Motions of Nonuniform Masses and Springs in a Straight Line. The case of two unequal masses connected by a spring has already been solved [Eq. (51)].

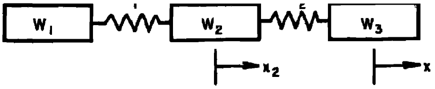

FIG. 30-34. Analysis of nonuniform trains (three masses).

Figure 30-34 shows the next step, with weights W_1, W_2, and W_3 connected by springs k_1 and k_2. Taking summation of forces of each mass in turn gives the equations

$$(W_1/g)(d^2x_1/dt^2) + k_1x_1 - k_1x_2 = 0 \tag{73}$$

$$(W_2/g)(d^2x_2/dt^2) - k_1x_1 + (k_1 + k_2)x_2 - k_2x_3 = 0 \tag{74}$$

$$(W_3/g)(d^2x_3/dt^2) - k_2x_2 + k_2x_3 = 0 \tag{75}$$

Assume $x_1 = a_1 \sin \omega t$, $x_2 = a_2 \sin \omega t$, etc., and substitute in the equations. This eliminates the time by cancellation of the factor $\sin \omega t$. Adding the equations together gives

$$(\omega^2/g)(W_1a_1 + W_2a_2 + W_3a_3) = 0 \tag{76}$$

By using Eqs. (73) and (75), a_1 and a_3 can be eliminated from (74) giving

$$\omega^4 - \omega^2 g\left[k_1\left(\frac{1}{W_1} + \frac{1}{W_2}\right) + k_2\left(\frac{1}{W_2} + \frac{1}{W_3}\right)\right] + \frac{g^2k_1k_2(W_1 + W_2 + W_3)}{W_1W_2W_3} = 0 \tag{77}$$

The two natural frequencies can be found by solving this quadratic for ω^2.

A system with four masses would result in a cubic equation for ω^2, etc. For systems with four or more masses, however, it is quicker to find the roots by an iteration method. An estimated value is obtained for ω^2 (see numerical example on page 1823), and a_1 is taken as 1. Equation (73) gives

$$a_2 = a_1 - (\omega^2/k_1g)W_1a_1 \tag{78}$$

Adding Eqs. (73) and (74) gives

$$a_3 = a_2 - \frac{\omega^2}{g}\frac{1}{k_2}(W_1a_1 + W_2a_2) \tag{79}$$

In a general problem, for the $(r + 1)$th amplitude

$$a_{r+1} = a_r - \frac{\omega^2}{g}\frac{1}{k_r}(W_1a_1 + W_2a_2 + \qquad + W_ra_r) \tag{80}$$

Thus, all the amplitudes can be found successively. It is convenient to arrange the computations in a table. When all amplitudes have been found, the results can be checked in Eq. (76). If there are n masses, the equation becomes

$$\frac{\omega^2}{g}\sum_{r=1}^{r=n} W_ra_r = 0 \tag{81}$$

Unless the estimated value used for ω^2 was exactly equal to one of the natural frequencies, Eq. (81) will not give a zero result. The indicated sum may be called the "remainder force," as it represents an external force which would have to be applied to the system to maintain the assumed vibration.

If the assumed value of ω is between zero and the first natural frequency, the remainder force is positive because of the positive value assigned to a_1. For values of ω between the first and second natural frequencies, the remainder force is negative, etc. Thus the sign of the remainder force indicates whether ω should be increased or decreased for the next trial. An experienced computer can often arrive at the correct result for the first natural frequency in two or three trials. The higher frequencies can be found by exactly the same procedure, but the number of trials tends to increase because the rate of variation of the remainder force with ω^2 is much greater.

Example: Consider the system shown in Fig. 30-35. In the fundamental mode of vibration, there can be only one "node" (stationary point). Since this will probably occur near the center of the train, a simplified two-mass system (Fig. 30-36) is formed by combining W_1 with W_2, W_3 with W_4, and connecting with a spring somewhat softer than k_2. From Eq. (51), the natural ω^2 of Fig. 30-36 is

$$\omega^2 = \frac{kg(W_a + W_b)}{W_aW_b} = \frac{30 \times 386(500 + 600)}{500 \times 600} = 42.4 \tag{82}$$

Table 30-2 shows the rest of the computation.

Table 30-2

W	$\frac{W\omega^2}{g}$	a	$\frac{W\omega^2a}{g}$	$\sum\frac{W\omega^2a}{g}$	k	$\frac{1}{k}\sum\frac{W\omega^2a}{g}$
First trial: $\omega^2 = 42.4$						
300	32.9	1.000	32.9	32.9	50	0.659
200	22.0	0.341	7.5	40.4	70	0.577
100	11.0	−0.236	−2.6	37.8	40	0.945
500	54.9	−1.281	−70.4	−32.6		
Fifth trial: $\omega^2 = 32.0$						
300	24.9	1.000	24.9	24.9	50	0.498
200	16.6	0.502	8.34	33.24	70	0.475
100	8.3	0.027	0.22	33.46	40	0.837
500	41.4	−0.810	−33.5	0		

Hence the lowest natural frequency is $\sqrt{32}/2\pi = 0.900$ cps, or 54 cycles per min.

Torsional Vibrations. In most machinery, power is transmitted by rotating shafts. Torsional (rotary) vibrations are likely to occur, especially if the motor or the load has nonuniform characteristics.

Figure 30-37 shows the simplest system of this kind, in which a shaft is fixed at one end and carries a flywheel at the other. The moment of inertia of the flywheel is I: in engineering units it is usually measured in pounds-inches-seconds squared. As an example, the moment of inertia of a homogeneous cylinder about its axis is $\frac{1}{2}mr^2$, where m is the mass of the cylinder and r is the radius. In vibration work, as in machine design generally, lengths are usually measured in inches. Thus, mass = weight/g, with weight in pounds and g = 386 in. per sec per sec. This gives the engineering unit of mass as pound-(seconds)^2 per inch; and with r in inches, the units of I will be pound-inch-(seconds)^2.

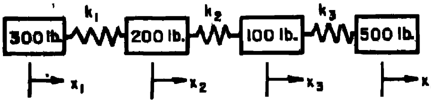

FIG. 30-35. Analysis of nonuniform trains (more than three masses).

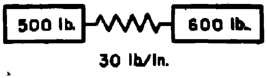

FIG. 30-36. Approximation for fundamental mode of Fig. 30-35.

k_t is the torsional spring constant of the shaft, measured in inch-pounds per radian of twist. For a solid cylindrical shaft of length L and diameter d, $k_t = \pi d^4 G/32L$, where G is the shear modulus of the material. For steel, G is often taken as 12×10^6 lb per sq in. although the accurate value is usually between 10.8 and 11.5.

For a hollow shaft, $\pi d^4/32$ is replaced by $\pi(d_0^4 - d_i^4)/32$. Formulas for noncircular shafts can be found in books on strength of materials or theory of elasticity. Much work has been done in testing and developing approximate formulas for torsional stiffness of crankshafts.[1,2,22] If found from a test, k_t = (torque, inch-pounds divided by angle of twist, radians).

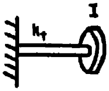

FIG. 30-37. Torsional vibration (one degree of freedom).

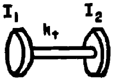

FIG. 30-38. Torsional vibration (shaft with two disks).

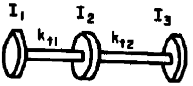

FIG. 30-39. Torsional vibration (shaft with three disks).

If ϕ is the angle of twist from equilibrium position in Fig. 30-37, the equation of motion may be found by considering the moments which act on the flywheel. This gives

$$I(d^2\phi/dt^2) + k_t\phi = 0 \tag{83}$$

This is exactly the same as Eq. (1), with W/g replaced by I and k by k_t. Thus, the natural frequency for torsional vibrations is

$$f_n = \frac{1}{2\pi}\sqrt{\frac{k_t}{I}} \tag{84}$$

All the methods and results developed for linear vibrations can now be applied to torsional cases. For a shaft with two disks (Fig. 30-38), the natural-frequency formula is

$$f_n = \frac{1}{2\pi}\sqrt{\frac{k_t(I_1 + I_2)}{I_1 I_2}} \quad \text{cps} \tag{85}$$

For a three-disk arrangement (Fig. 30-39), there are two values of $f_n = \omega/2\pi$, with ω^2 being found from the quadratic:

$$\omega^4 - \omega^2\left[k_1\left(\frac{1}{I_1}+\frac{1}{I_2}\right)+k_2\left(\frac{1}{I_2}+\frac{1}{I_3}\right)\right]+\frac{k_1k_2(I_1+I_2+I_3)}{I_1I_2I_3}=0 \qquad (36)$$

For more than three disks, the tabular method of iteration can be used as in Table 30-2, with W/g replaced by moments of inertia I and spring constants k by torsional constants k_t. Such tables are known as "Holzer tables."

Installations of internal-combustion or diesel engines, or reciprocating steam engines, are especially subject to trouble from torsional vibration because of the pulsations inherent in using cylinder pressures to create turning moments. Large vibrations can build up when the operating speed coincides with a natural frequency. Also, since the torque is not a pure sine wave, it has harmonic components of two, three, etc., times the fundamental frequency. Thus, vibrations can occur not only when running at the natural frequency (often called the "critical speed") but at many fractions of this speed. For a steam engine, "2-cycle" engine, or compressor, there is 1 cycle of torque per revolution; for 4-cycle gasoline engines, the cycle of torque requires two revolutions.

If there are several cylinders, the combined effect of all the torques must be considered. For some harmonic orders, the torques may cancel provided running conditions are the same in all cylinders. However, there will always be some orders where the effect on vibration is cumulative. Consider, for example, a 6-cylinder 4-cycle engine installation in which one natural frequency for torsional vibration is 2,100 cycles per min. For each cylinder, the torque cycle requires two revolutions. The sixth harmonic will then have 6 cycles in two revolutions or 3 cycles in one revolution. This is therefore known as the "third-order" component. The third-order components of all the cylinders in the above engine will be in unison, regardless of firing order, because there are also three firings per revolution. Hence, heavy torsional vibration is likely to occur with the engine running at 2,100/3 = 700 rpm since the third-order torques will give a disturbing frequency of 2,100 cycles per min at this speed. Vibration is also likely at speeds which are multiples of 700 rpm.

The main objection to torsional vibration is, of course, the likelihood of breaking crankshafts or other components owing to high fatigue stresses. If there are gears in the drive, the "chattering" caused by torsional vibration can be very destructive. Many breakdowns caused by such vibrations have occurred in the past.

Textbooks on vibration[1,2] give extended consideration to this problem. Methods of reducing a multicylinder engine to an idealized system of shafts and disks are discussed, and examples of natural-frequency calculations are shown. Fairly accurate methods are available for analyzing the torque into its harmonic components, estimating the amount of damping (from elastic hysteresis, propeller action, etc.), and thus computing the maximum amplitude of torsional vibration which will occur at a given critical speed.

In most cases, the inherent damping in the system is too small to prevent dangerous fatigue stresses from being built up by vibration at one or more of the critical speeds. If the engine is required to operate only over a restricted range of speeds or at a constant speed, it is possible to adjust the elastic and mass relations so that no important critical speed falls within the operating range. On existing installations, it may be possible to rearrange the severity of several of the critical speeds by changing the firing order of the engine. However, if the engine must operate over a wide speed range, the only effective method of controlling vibration amplitudes is by the use of some sort of damper. Many devices have been tried for this purpose. One of the oldest is the "Lanchester damper," consisting of two flywheels mounted on the engine shaft and coupled to it only through friction on spring-loaded pads. When the engine runs smoothly, the disks run with it. If a vibration occurs, superposed on regular running, the disks tend to maintain constant speed owing to their inertia. The relative motion absorbs energy by a rubbing action, thus reducing the amplitude of vibration. While the device is effective when properly designed and adjusted, it has the weakness that the friction must be held within fairly narrow limits. If the disks are too loose or too tight, little damping can be secured. Thus an adjustment and maintenance problem exists. The classic example of this was a near disaster to the dirigible Graf Zeppelin: on one attempted oceanic flight, most of the airship's engines suffered broken crankshafts because an uninformed mechanic had excessively tightened the vibration dampers.

As mentioned in the section on the dynamic vibration absorber, a "torsional pendulum" or floating counterweight can be designed to eliminate vibration due to a specified torque harmonic at any speed of the engine. This has been extensively applied in aircraft engines.[2]

In the automobile industry, dampers using rubber in shear between a pair of disks and the crankshaft are very popular. The rubber supplies both spring and damping action. Again, proper design and adjustment are essential for correct functioning of such a damper.

VIBRATIONS OF BODIES WITH DISTRIBUTED MASS AND ELASTICITY

Previously, systems with concentrated masses and weightless springs have been the only types considered. A system with distributed mass can be approximated by dividing it into a number of parts, lumping the mass and spring factors, and treating it as a problem in several degrees of freedom. However, by means of partial differential equations, the completely distributed case can be solved for many cases where the geometric form is sufficiently simple.

Fig. 30-40. Longitudinal vibration of uniform bar with fixed ends.

Longitudinal Vibrations in Bars, Coil Springs, and Gas or Liquid Columns. As an example of longitudinal vibrations, consider longitudinal vibrations in a uniform elastic bar. The solution, when obtained, can be applied immediately to axial vibrations in coil springs.

Figure 30-40 shows a uniform elastic bar with fixed ends and coordinates. L = length, A = cross-sectional area, E = modulus of elasticity, w = density of material, x = distance from one end to any point. Let u = displacement of the cross section at x from its position of static equilibrium. During a vibration, each cross section of the bar moves through a certain amplitude, which varies along the length of the bar. Thus u is a function of both x and time t.

If such a bar is subjected to an axial pull P, the elongation is obtained from the formula $\delta = PL/AE$. Thus, $P = AE\delta/L$. δ/L is the unit strain (inches per inch); in terms of u, $\delta/L = \partial u/\partial x$. (If u = constant, all sections of the bar move the same distance, and there is no strain.) Thus the elastic force P in the bar equals $AE\partial u/\partial x$. Figure 30-40*b* shows the forces acting on an element of the bar of length dx. The elastic force to the left is $AE\partial u/\partial x$. The force to the right is $AE[(\partial u/\partial x) + (\partial^2 u/\partial x^2)\,dx]$, reflecting the change in u with x. Applying the principle that force equals mass times acceleration gives

$$AE\frac{\partial^2 u}{\partial x^2}\,dx = \frac{wA\,dx}{g}\,\frac{\partial^2 u}{\partial t^2}$$

Removing common factors,

$$\frac{\partial^2 u}{\partial x^2} = \frac{w}{Eg}\,\frac{\partial^2 u}{\partial t^2} \tag{87}$$

Partial differential equations of this sort are solved by assuming that u is a product of two functions, one containing x only and the other t only. Thus, let

$$u = U \sin \omega t$$

where U is a function of x. Substituting in Eq. (87) and canceling the common factor $\sin \omega t$,

$$(d^2U/dx^2) + (w\omega^2/Eg)U = 0 \tag{88}$$

Letting $\Omega = w\omega^2/Eg$, the solution of this ordinary differential equation is known to be [see Eqs. (1) and (2)]

$$U = C_1 \cos \Omega x + C_2 \sin \Omega x \tag{89}$$

where C_1 and C_2 are constants which must be adjusted to fit the end conditions of the bar. In Fig. 30-40, it is necessary to have $U = 0$ when $x = 0$ and when $x = L$. The first condition makes $C_1 = 0$. For the second, $C_2 = 0$ would give $U = 0$, a nonvibrating state of the bar. The alternative is to take $\sin \Omega L = 0$. This gives $\Omega L = \pi, 2\pi, 3\pi$, etc., from which the unknown frequency factor ω can be found. Thus, the natural frequencies for longitudinal vibration of the bar are

$$f_s = \frac{\omega}{2\pi} = \frac{s}{2L}\sqrt{\frac{Eg}{w}} \qquad \text{where } s = 1, 2, 3, \ldots . \tag{90}$$

Figure 30-40c shows the mode or amount of vibration at points along the length of the bar. Since $U = C_2 \sin s\pi x/L$, the constant C_2 gives the maximum vibrational amplitude (which is determined when the vibration is started). For the fundamental mode, U is given by half of a sine wave. At the second frequency, U is a full sine wave; hence there is a node at the center of the bar, and the two ends always have displacements in opposite directions.

As an example, when Eq. (90) is applied to the case of a steel bar 6 in. long, $E = 30 \times 10^6$ psi, $g = 386$ in. per sec per sec, $w = 0.284$ lb per cu in., giving $f = 16{,}800$ cps for the fundamental frequency. This is about six octaves above middle C on the musical scale.

The practical applications of Eq. (90) occur most often in two cases: the "organ pipe," where the natural frequency of a column of gas or liquid is desired, and the coil spring. For a gas, the modulus of elasticity may be determined from the gas laws. If the cross section A of the pipe is constant, the unit strain

$$dx/L = A\,dx/AL = dv/v$$

where v is the volume. For a small change dp in the pressure, the modulus of elasticity or "spring constant" may be found from

$$E = \text{change in stress/change in strain} = -v\,dp/dv$$

The minus sign is used to make the modulus a positive quantity, since dp and dv will always have opposite signs. Since the alternations of pressure in the organ pipe occur very rapidly, the process will be adiabatic rather than isothermal. Using pv^n = constant, $E = -v\,dp/dv = pn$. For air at atmospheric pressure, $n = 1.4$ and $p = 14.7$ psi, giving $E = 20.6$ psi.

For the coil spring, let d = wire diameter, D = mean coil diameter, G = shear modulus, N = number of active turns, w = density of wire material, lb per cu in.

$$\text{Spring constant } k \text{ of the coil spring} = \text{load/deflection} = Gd^4/8ND^3 \tag{91}$$

Let W = weight of active turns of the spring. Then (approximately)

$$W = (\pi d^2/4)(\pi DN)(w)$$

Equation (90) must be put in terms of k and W for the uniform bar. Since $k = AE/L$ for the straight bar and $W = wAL$, Eq. (90) can be written as

$$f = \frac{s}{2}\sqrt{\frac{AEg}{AwL^2}} = \frac{s}{2}\sqrt{\frac{kg}{W}} \tag{92}$$

Introducing k and W for the coil spring gives

$$f = \frac{s}{2\pi}\frac{d}{ND^2}\sqrt{\frac{Gg}{2w}} \qquad \text{where } s = 1, 2, 3, \ldots, \tag{93}$$

as the natural frequencies for a coil spring fixed at both ends. The frequency is independent of any initial load (compression or tension) which may exist in the spring. As most springs are made of steel, let $G = 11.5 \times 10^6$ psi, $g = 386$ in. per sec per sec, $w = 0.284$ lb per cu in. The lowest natural frequency of a steel coil spring is thus found to be

$$f_1 = 14{,}100d/ND^2 \qquad \text{cps} \tag{94}$$

When springs are used in high-speed machinery, malfunctioning may occur due to "surges," or axial vibrations at the natural frequency of the spring. If the spring is used to maintain pressure on a cam follower, as in poppet valves for internal-combustion engines, the cam lift curve is ordinarily not simple harmonic. It will therefore contain harmonics at multiples of the fundamental cam frequency. In such a case it is considered good practice to have the natural frequency of the spring from 15 to 20 times the maximum operating frequency of the cam. This may require working the spring material at the maximum shearing stress allowable under the given working conditions, as can be readily shown. The maximum shearing stress in the spring is

$$s_{\max} = (8PD/\pi d^3)C \tag{95}$$

where C is the "Wahl factor," or stress-concentration factor. For well-designed springs, C does not vary greatly. The spring rate of the spring is given by Eq. (91). In most applications, the values of k and the maximum load P will be set by the duty which the spring must perform. Using Eq. (91) to rewrite Eq. (95) gives

$$s_{\max} = \frac{PCG}{\pi k}\frac{d}{ND^2} \tag{96}$$

Equation (94) shows that to raise the natural frequency of a steel spring requires an increase in the quantity d/ND^2. If P and k are held at constant values, it follows from Eq. (96) that the maximum stress will go up in the same proportion as the natural frequency.

Many other cases of free vibration of elastic bodies have been solved. Results for the commonly encountered shapes are tabulated at the end of this section (pages 1831 to 1835).

General Methods for Difficult Problems. Mathematicians have solved many cases in addition to those recorded above, such as movement of rigid bodies suspended in various ways, vibrations in elastic spheres, cylinders, plates, disks, shells and tubes, and vibration of air or gases in containers of simple shapes.[34 to 37] In general, the results are not presented in readily available formulas.

Energy Method. Rayleigh's Method. In many cases, the "energy method" is used. A vibration represents a continual interchange of energy between moving masses and elastically strained members. If friction is neglected, the kinetic energy at mid-position of a vibration must equal the strain (potential) energy at the end positions. By assuming a simple harmonic motion, calculating the two energies and equating them, the natural frequency can be found.

"Rayleigh's method" consists in extending this procedure to elastic bodies in general. In such a case, all parts of the body do not vibrate with the same amplitude, but the true shape or mode is not known in advance. Rayleigh[34] developed the procedure of assuming some reasonable shape, calculating the energies, and in this way finding the natural frequency. If several shapes are tried, the one giving the lowest frequency is most nearly correct. This is because the true shape is the one in which the body is distorted with the least amount of strain energy. Ritz added the refinement of assuming the trial shape in the form of an equation with a parameter, then varying the parameter until a minimum natural frequency is obtained.

"Critical Speed" for Lateral Vibration of Rotors. Consider a case in which it is desired to find the lowest natural frequency for lateral vibration of a rotor, as in a steam turbine. Usually, the stiffness varies along the shaft. The latter is divided into a sufficient number of sections, and the weight and stiffness factors of each section are computed. The total deflection at each section is then found, this being a problem in strength of materials. If it is assumed that the shape of the lowest-frequency vibration is the same as this statical deflection curve, the frequency formula is

$$f_1 = \frac{1}{2\pi}\sqrt{\frac{g\Sigma W_i\delta_i}{\Sigma W_i\delta_i^2}} \qquad \text{cps} \qquad \text{where } i = 1, 2, \ldots, n \tag{97}$$

When converted to cycles per minute, this is frequently called the "critical speed."

Dynamically Equivalent Systems. Frequently, complicated elements can be reduced to simpler ones which are dynamically equivalent. In Fig. 30-1, if a coil or an axially loaded bar is used for the spring, its weight can be included in the calculations by adding one-third the spring weight to w. If the spring action is obtained by bending, the factor varies from about one-quarter to one-half, depending on the shape assumed for the vibration. In analyzing torsional vibrations, the reduction of rotating machinery and engines to a system of simple shafts and disks has been mentioned. Kemler and Freberg[34] give numerous examples of reduction to dynamically equivalent systems. When machinery contains shafts geared at different speeds, an equivalent system all on one shaft can be set up.

MORE COMPLICATED CASES OF SEVERAL DEGREES OF FREEDOM

There are many practical problems of vibration in systems of several degrees of freedom in which the foregoing simplified methods of analysis cannot be applied. The following list is representative of this class:

1. Higher frequency vibrations of a nonuniform beam, as in ship hulls, steam turbine rotors, etc.
2. Combined bending and torsional vibrations in airplane propellers, wings, fuselages, etc.
3. Two- or three-dimensional vibrations of an automobile structure, with sprung and unsprung weights and passengers on spring seats

Powerful mathematical methods have been developed and solutions obtained for typical problems of the above types. The treatments are too lengthy to reproduce here, but References 1, 2, and 23 to 26 listed on pages 1836 and 1837 give the best available procedures. In some cases, punched-card computing machines can be used.

As an example of an unsolved problem, the two- or three-dimensional motions of a chain or cable suspended at two points may be mentioned.[27,28]

SELF-INDUCED VIBRATIONS

Forced vibrations previously discussed have been caused by rotating or reciprocating unbalance, magnetic action, etc. If such a system is clamped, it still experiences sinusoidal disturbing forces. However, there are many vibrating systems in which, deliberately or accidentally, the forces driving the motion are caused to fluctuate by the motion itself. When the motion stops, there is no independent periodic force. Such cases are called self-induced vibrations. There are many familiar examples:

1. The bowing of a violin string, the "chattering" of brakes and cutting tools, and the screech of dry rubbing surfaces are cases of vibration due to friction. In each case, a driving member is caused to move at fairly uniform speed over the vibrating element with dry friction between the two. Such a friction force has the characteristic that it varies inversely with the rubbing speed. When the two elements move in the same direction, the relative rubbing speed is less, and a large force exists to help the motion. When the vibrating element reverses, the relative velocity is greater; and while friction now opposes the motion, its magnitude is less. Thus, over a complete cycle there is a net input of energy to the vibrating system, and the motion maintains itself. In preventing such noises, lubrication is effective because liquid friction has an opposite characteristic: it varies directly with velocity.

2. The waving or flapping of a flag and the humming noise of telephone wires exposed to wind are due to formation of eddies in the stream of air. These are discharged alternately from the two sides of the object, giving an alternating force which maintains the vibration. Such motions are occasionally serious,[4] as in the "fluttering" of airplane wings and tails, or the collapse of the Tacoma Narrows Bridge.

3. The flow of liquids or gases through spring-loaded valves will nearly always cause vibrations of the valve member to occur. Figure 30-41 shows air being forced at a uniform rate into a closed chamber, the only outlet being partially closed by a reed at B. Assume the reed is vibrating, causing a variation in the size of the opening through which air escapes. When the reed is passing through center in an outward or opening direction, the pressure in the chamber is higher than average, as the outlet has recently been restricted. When the reed returns inward, the pressure is lower as the opening has been larger. Thus, the total effect is to maintain the vibration of the reed. In order to suppress the vibration, it is necessary to apply some sort of damping resistance to motion of the reed.

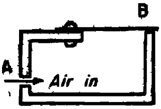

FIG. 30-41. Vibration of musical reed or spring-loaded valve.

Vibration can also occur with air flowing in the opposite direction. In this case, air flowing under the reed causes a suction by Bernoulli's principle. This draws the reed down and closes the passage. The pressures on the two sides of the reed then equalize; the reed moves upward, and the cycle repeats.

The same effect can be created by a loose obstruction. The stream carries the object into a position in which it cuts off the flow. Under static conditions, pressures equalize, and the obstruction falls away, permitting the cycle to repeat. Noisy vibrations of this sort often occur in faucets with loose washers.

4. Automatic control systems on temperature, speed of rotation, etc., frequently "hunt" or fluctuate about the desired control point rather than settling to a steady value. This is because there is a time lag between the controller and the quantity controlled, leading to overshooting and overcorrection. Performance can be improved by decreasing the time lags and by introducing damping at the proper point of the system.

All the above matters are more thoroughly treated by Den Hartog.[2]

NONLINEAR SYSTEMS

Frequently, vibration problems involve a spring whose force cannot be adequately represented by k times the displacement. k may be a function of time, as in torsional vibrations of the connecting-rod drive systems of locomotives; or the spring may become relatively softer or harder with deflection. Forced vibration of systems of the latter type can best be analyzed by the methods of Rauscher.[32] Figure 30-42 shows a resonance curve for a system with a "hard" spring. Free vibrations are given by the curve AB; frequency will increase with amplitude because of increasing stiffness in the spring. Forced vibrations under increasing speed will follow the curve CG to D. For further increase in speed, the amplitude drops suddenly to E, and the system becomes relatively quiet. Under decreasing speed, the amplitude follows EF, then suddenly jumps to G, then moves down to C. It never becomes as large as the peak values for increasing speed.

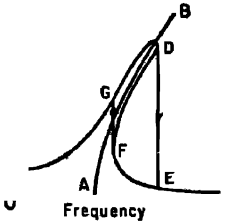

FIG. 30-42. Forced-vibration characteristics of system in which spring rate increases with deflection.

For mathematical treatments of the time-variable and nonlinear systems, the general books of Timoshenko and Den Hartog[1,2] should be consulted.

NOMENCLATURE

NOTE: In vibration work, lengths are usually in inches, weights and forces in pounds, and time in seconds. Mass = weight/g = pounds/386, since g = 386 in. per sec per sec

A = cross-sectional area of a bar or surface area of a membrane
a, b = dimensions of rectangular membrane or plate
c = damping constant = force/velocity = lb-sec/in.
c_c = critical damping = $2\sqrt{kw/g} = 2(W/g)\omega_n$
db = decibels (measurement of sound intensity)
δ = deflection of elastic element
δ_{st} = statical deflection = W/k
D = plate constant = $Eh^3/[12(1-\mu^2)] = 2.75 \times 10^6 h^3$ for steel
E = modulus of elasticity in tension or compression. For a gas, $E = pn$, where p = pressure, and n is the adiabatic exponent in pv^n = const. E = 20.6 lb/sq in. for atmospheric air
f = frequency, cps
f_n = natural frequency of a vibrating system, cps
f_1 = lowest natural frequency
F_0 = maximum dynamic force transmitted to foundation by vibrating system
g = acceleration of gravity = 386 in./sec/sec
G = modulus of elasticity in shear
h = thickness of a plate, in.
k = spring rate, lb/in. of deflection
k_t = torsional spring rate = in.-lb/radian
L = length of bar or string
N = revolutions per minute of a rotor
P_0 = maximum value of disturbing or shaking force on a machine
r = radius of a circle or mean radius of a ring
$\bar{r}$ = radius from swing point to center of gravity of a pendulum
s = 1, 2, 3, etc. = successive modes of vibration
TR = transmissibility ratio of a suspension = force on foundation/force on machine = F_0/P_0
t = time, sec
T = period of a vibration, sec, or tension in a cord, lb
T_1 = tension, lb/lin in. around the boundary of a membrane
v = velocity = dx/dt; velocity of sound in a material = $\sqrt{Eg/w}$
W = weight, lb
w = density of a material, lb/cu in. = 0.284 for steel
w_1 = weight of string or bar, lb/lin. in.
w_u = unit weight of a membrane or plate, lb/sq in.
x = displacement of a vibration; velocity = dx/dt and acceleration = d^2x/dt^2
μ = Poisson's ratio = 0.3 for steel
ω = angular velocity, radians/sec; $\omega = 2\pi N/60$
$\omega_n = \sqrt{kg/W}$

NATURAL FREQUENCIES OF ELASTIC BODIES

(Natural frequencies of assembled systems are given in the preceding text.)

Stretched Strings.

String of length L, tension T:

$$f_n = (s/2L)\sqrt{Tg/w_1} \qquad \text{where } s = 1, 2, 3, \ldots \tag{98}$$

Chain or Cord Suspended by One End.

Uniform chain or flexible cord of length L, suspended by one end, hanging vertically (Fig 30-43):

$$y = CJ_0(z) \qquad f_n = (z_s/4\pi)\sqrt{g/L} \qquad z = z_s\sqrt{x/L} \tag{99}$$

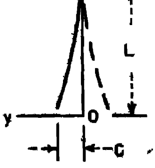

FIG. 30-43. Free vibration of chain or cord suspended by one end.

$J_0(z)$ is Bessel's function of order zero, and z_s represents the successive roots of $J_0(z) = 0$.[27,31] The first four values of z, are 2.4048, 5.5201, 8.6537, and 11.7915. For higher modes, z_s approaches $\pi(s - 0.25)$.

Longitudinal Vibrations in Uniform Bars or Gas Columns of Length L. Ends both fixed or both free:

$$f_n = (s/2L)\sqrt{Eg/w} \qquad \text{where } s = 1, 2, 3 \ldots \tag{100}$$

One end fixed, one free:

$$f_n = (s/4L)\sqrt{Eg/w} \qquad \text{where } s = 1, 3, 5, \ldots \tag{101}$$

One end fixed, other end attached to concentrated weight W_2. If weight of bar $wAL \leq W_2$,

$$f_n = \frac{1}{2\pi}\sqrt{\frac{AEg}{L[W_2 + (wAL/3)]}} \tag{102a}$$

If $wAL > W_2$, use

$$f_n = (\beta/2\pi L)\sqrt{Eg/w} \tag{102b}$$

where β is a root of $\beta \tan \beta = wAL/W_2$ (see following table from Reference 1).

$\frac{wAL}{W_2}$	0.01	0.10	0.30	0.50	1.0	2.0	5.0	10.0	∞
β	0.10	0.32	0.52	0.65	0.86	1.08	1.32	1.42	$\pi/2 = 1.57$

Torsional Vibration of Uniform Bars.

Torsional vibration of uniform bars of circular cross section and length L. (103) Replace E by G in cases (100) to (101).

Lateral Vibration of Uniform Bars of Length L:

$$f_n = (\alpha^2/2\pi L^2)\sqrt{EIg/w_1}$$

Both ends simply supported (hinged-hinged):

$$\alpha^2 = \pi^2 s^2 = 9.87, 39.48, 88.83, 157.9, 246.7, \ldots \tag{104}$$

Both ends free; bar lying on frictionless surface or supported at nodal points. $\cos \alpha \cosh \alpha = 1$:

$$\alpha^2 = 22.37, 61.67, 120.91, 199.8, 298.6, \ldots \tag{105}$$

If bar is floated in liquid, as a ship hull, some allowance should be made for weight of water moved by the vibration.

Both ends built in (fixed-fixed). Same results as Eq. (105). (106)

Cantilever (fixed-free). $\cos \alpha \cosh \alpha = -1$:

$$\alpha^2 = 3.516, 22.03, 61.70, 120.9, 199.8, 298.6, \ldots \tag{107}$$

One end fixed, other end hinged. $\tan \alpha = \tanh \alpha$:

$$\alpha^2 = 15.42, 49.97, 104.24, 178.3, 272.0, \ldots \tag{108}$$

One end hinged, other end free. Same results as Eq. (108). (109)

Wedge (Fig. 30-44)

Lateral, in plane of paper:

$$f_1 = \frac{0.2442d}{L^2}\sqrt{\frac{Eg}{w}} = 49{,}300\frac{d}{L^2} \qquad \text{for steel} \tag{110}$$

Perpendicular to plane of paper:

$$f_1 = \frac{0.3266t}{L^2}\sqrt{\frac{Eg}{w}} = 65{,}950\frac{t}{L^2} \qquad \text{for steel} \tag{111}$$

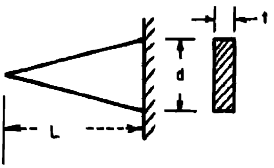

FIG. 30-44. Vibrations of wedge (large end fixed).

Lateral vibration of conical bar, length L, base diameter d, built in at base:

$$f_1 = \frac{0.3469d}{L^2}\sqrt{\frac{Eg}{w}} = 70{,}000\frac{d}{L^2} \qquad \text{for steel} \tag{112}$$

Circular Ring (Fig. 30-45)
Pure radial vibration:

$$f_n = \frac{1}{2\pi r}\sqrt{\frac{AEg}{w_1}} = \frac{1}{2\pi r}\sqrt{\frac{Eg}{w}} = \frac{32{,}100}{r} \quad \text{for steel} \tag{113}$$

Pure torsional vibration:

$$f_1 = \frac{1}{2\pi r}\sqrt{\frac{EgI_x}{w(I_x + I_y)}} = \frac{22{,}700}{r} \quad \text{for steel, circular cross section} \tag{114}$$

Flexural vibrations in plane of ring:

$$f_n = \frac{1}{2\pi r^2}\sqrt{\frac{EgI_y}{wA}\,\frac{s^2(s^2-1)^2}{s^2+1}} \tag{115}$$

where $s = 2, 3, 4, \ldots$

Flexural vibrations perpendicular to plane of ring:

$$f_n = \frac{1}{2\pi r^2}\sqrt{\frac{EgI_x}{wA}\,\frac{s^2(s^2-1)^2}{s^2+1+\mu}} \tag{116}$$

μ = Poisson's ratio, and $s = 2, 3, 4, \ldots$

Free-free cut rings.[30] (117)

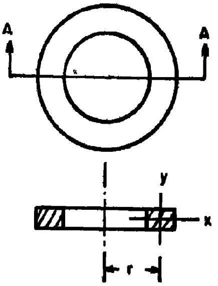

Fig. 30-45. Circular ring.

Membranes

Circular membrane. Let d = number of nodal diameters and c = number of nodal circles, including boundary.

$$f_n = (F_{dc}/r)\sqrt{gT_1/w_a} \tag{118}$$

where values of F_{dc} appear in Table 30-3.

Table 30-3. Values of F_{dc}

c	$d = 0$	$d = 1$	$d = 2$	$d = 3$	$d = 4$	$d = 5$
1	0 3826	0 6099	0 8173	1 0153	1 2074	1 3974
2	0 8785	1 1167	1 3396	1 5534	1 7609	1 9639
3	1 3773	1 6191	1 8494	2 0717	2 2875	2 4987
4	1 8767	2 1204	2 3548	2 5821	2 8037	3 0211
5	2 3763	2 6213	2 8584	3 0892	3 3147	3 5364
6	2 8761	3 1220	3 3609	3 5942	3 8226	4 0475
7	3 3760	3 6224	3 8627	4 0081	4 3290	4 5563
8	3 8759	4 1226	4 3642	4 6010	4 8337	5 0632

Rectangular membrane:

$$f_1 = \frac{F}{a}\sqrt{\frac{gT_1}{w_a}} \qquad f_n = \frac{1}{2}\sqrt{\frac{gT_1}{w_a}\left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right)} \tag{119}$$

where $m = 1, 2, 3, \ldots$; $n = 1, 2, 3, \ldots$.

Dimensions	F
$a \times a$	0 7071
$1\ 5a \times a$	0 6008
$2a \times a$	0 5589
$3a \times a$	0 5270
$\infty \times a$	0 5000

Membranes of other shapes:

$$f_1 = H\sqrt{gT_1/w_aA} \tag{120}$$

Shape	*H*
Circle	0.6782
Semicircle	0.7644
Quadrant of circle	0.7243
60-deg sector of circle	0.7348
Square	0.7071
Rectangle 3 × 2	0.7359
Rectangle 2 × 1	0.7905
Rectangle 3 × 1	0.9129
Equilateral triangle	0.7598
Isosceles right triangle	0.7906

Plates

Rectangular plate, simply supported edges:

$$f_n = \frac{\pi}{2}\left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right)\sqrt{\frac{gD}{wh}} \qquad \text{where } m = 1, 2, 3, \ldots, n = 1, 2, 3, \ldots \tag{121}$$

Square plate, free edges:

$$f_n = (F/a^2)\sqrt{gD/wh} \qquad \text{where } F = 2.244, 3.272, 3.805, \ldots \tag{122}$$

Circular plate, clamped boundary, in vacuo:

c = number of nodal circles, including boundary

d = number of nodal diameters

$$f_n = (F/a^2)\sqrt{gD/wh} \tag{123}$$

Values of F

c	$d = 0$	$d = 1$	$d = 2$
1	1.625	3.377	5.545
2	6.331		
3	14.15		

In case plate is vibrating in a liquid of density w_L, the first frequency becomes

$$f_1 = \frac{1.625}{a^2\sqrt{1+\beta}}\sqrt{\frac{gD}{wh}} \qquad \text{where } \beta = 0.6689(w_L/w)\,(a/h)$$

For a circular plate with free edges, Eq. (123) may be used. The values of (124) are shown in the following table:

c	$d = 0$	$d = 1$	$d = 2$	$d = 3$
0	......	.....	0.836	1.946
1	1.4445	3.266	5.609	8.421
2	6.131	9.527		

For a circular plate, fixed at center, Eq. (123) may again be used. The (125) lues of F are shown in the following table:

c	$d = 0$	$d = 1$	$d = 2$	$d = 3$
0	0.597	0	0.836	1.946
1	3.328	3.266	5.609	8.421
2	9.658	9.527		
3	19.05			

At large amplitudes of vibration, frequencies increase slightly because of stretching in the middle plane of the plate.

Turbine Disks.

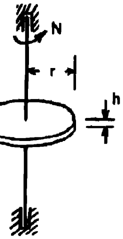

FIG. 30-46. Turbine disk.

Turbine disks, fixed at center (Fig. 30-16):

$$\left.\begin{aligned} f_n &= \sqrt{f_1^2 + f_2^2} \\ f_1^2 &= (F_1/r^4)(gD/wh) \quad \text{due to elastic force} \\ f_2^2 &= KN^2/10{,}000 \quad \text{due to rotation} \end{aligned}\right\} \tag{126}$$

	F_1				K			
c	$d = 0$	$d = 1$	$d = 2$	$d = 3$	$d = 0$	$d = 1$	$d = 2$	$d = 3$
0	0.357	0	0.734	3.95	0	2.78	6.53	11.25
1	11.09	10.69	30.65	71.94	9.17	16.53	24.86	34.17

SPRING CONSTANTS

Linear Spring Constants. Formulas for linear spring constants, pounds per inch deflection, and equivalent masses are listed in the following material.

Any linear spring:

$$k = \text{load, lb/deflection, in.} \tag{127}$$

Springs in parallel:

$$k_e = \Sigma k \tag{128}$$

Two springs in series:

$$k_e = k_1k_2/(k_1 + k_2) \tag{129}$$

Uniform bar axially loaded. Area A, length L:

$$k = AE/L \tag{130}$$

Add one-third weight of bar at each end.

Coil spring, axial deflection. Wire diameter d, mean coil diameter D_c, n active turns:

$$k = d^4G/8nD_c^3 \tag{131}$$

Add one-third weight of spring at each end.

Air under piston in cylinder. Length L, area A, pressure p:

$$k = 1.4Ap/L \tag{132}$$

Cantilever beam:

$$k = 3EI/L^3 \tag{133}$$

Add 23 per cent of beam weight at free end.

Beam loaded at center. Simple supports (hinged-hinged).

$$k = 48EI/L^3 \tag{134}$$

Add 48 per cent of beam weight at center.

Beam with built-in ends, loaded at center:

$$k = 192EI/L^3 \tag{135}$$

Add 37 per cent of beam weight at center.

Simply supported beam of length L, loaded at distance a from one end, b from other end:

$$k = 3LEI/a^2b^2 \tag{136}$$

Torsional Spring Constants. Formulas for torsional spring constants (inch-pounds per radian) and equivalent moments of inertia are given below.

Any torsional spring:

$$k_t = \text{moment, in.-lb/angle of rotation, radians} \tag{137}$$

Coil spring in torsion. Wire diameter d, mean coil diameter D_c, n active turns:

$$k_t = Ed^4/64nD_c \tag{138}$$

Uniform circular solid shaft. Length L, diameter d:

$$k_t = \pi Gd^4/32L \tag{139}$$

Add one-third moment of inertia of shaft at each end.

Hollow circular shaft. Length L, diameters d_1 and d_2:

$$k_t = \pi G(d_2^4 - d_1^4)/32L \tag{140}$$

Add one-third moment of inertia of shaft at each end.

AND DONALD H. VANCE

Executive Engineer, The Korfund Co., Inc.

NOMENCLATURE

C = coefficient of viscous damping = damaging force/velocity, lb-sec/in.
C_c = coefficient of critical damping = $2\sqrt{kW/g}$
$\dfrac{C}{C_c}$ = damping factor = $(c/2)\sqrt{g/kW}$
e = crank radius
f_N = natural frequency of spring support = $188\sqrt{1/\delta_{st}}$ cycles per min
f_D = disturbing frequency
F = magnitude of shaking force ($F \sin \omega t$)
F_T = force transmitted
F_N = force transmitted at resonance
g = acceleration of gravity = 32.2 ft/sec^2
k = spring constant W/δ_{st} lb per in.
r = frequency ratio f_D/f_N
t = time
T = period = $1/f$
T_D = period of damped free vibration with periodic damping
T_N = natural period
W = weight, lb
w = weight of reciprocating part
x = displacement from neutral position during vibration
x_{st} = F/k spring deflection due to static action of the magnitude F of the shaking force $F \sin \omega t$
x_{nst} = spring deflection due to static action of the shaking force at resonance
X = amplitude of forced vibration undamped
X_D = amplitude of forced vibration damped
X_N = resonant amplitude of forced vibration $F/c\omega_N$
δ_{st} = static deflection W/k, in.
ω = angular frequency
ω_N = natural angular frequency = $2\pi f_N$
ω_D = natural angular frequency damped

VIBRATION CONTROL

General Theory. Vibration problems occur in every field of engineering and in practically every type of plant or industry. While the presence of vibration is usually perceptible to the human senses, its source is not always easily determined. General vibration disturbances may be created by the operation of machinery within a plant, in which case the treatment of the problem might be classed as positive isolation, or the vibration may be transmitted to a plant from outside sources, in which case the treatment of the problem within the building might be defined as negative isolation.

Since it is not always possible or profitable to design machinery which will be in complete balance through its entire range of operation, it can be expected that practically every machine or piece of equipment containing moving parts will create vibration. Whether or not the vibration will be of sufficient intensity to become a hazard to the building structure, to personnel and adjacent equipment, or to neighboring localities can be determined only through thorough consideration of all aspects of the proposed installation.

Some of the benefits which may be derived from the control of vibration are listed and briefly described below.

1. *Reduction of Vibration Transmission.* By correct application of vibration-engineering principles and vibration control, a machine, which might ordinarily cause considerable transmission of unbalanced forces if mounted solidly, may in many cases be operated with such a reduction in transmitted force that its vibration cannot be detected by sensitive vibration instruments.

2. *Increased Efficiency and Lengthened Life of Machine.* Practical experiments have indicated that a valuable portion of the energy lost in transmitting vibration to a rigid supporting structure may be saved through the use of resilient mountings which periodically store rather than dissipate energy. The application of resilient supports also reduces the internal stresses within the structure of the machine by allowing freedom of motion resulting in increased machine life.

3. *Reduced Construction and Installation Cost.* If a vibrating machine is rigidly bolted to a foundation, the unbalanced forces causing the vibration will be transmitted to the foundation undiminished, and excessive stresses may be set up in the machine. Through the correct application of vibration control, the transmission of forces to the foundation and the creation of stresses within the machine can be greatly reduced. A considerable saving in construction and installation cost may, therefore, be realized through the employment of smaller foundations and lighter supporting structures. An additional saving is also realized through reduced maintenance of the equipment resulting from the relief of stresses within the vibrating machine.

4. *Improved Working Conditions.* Excessive vibration and the noise which generally accompanies it have a very decided influence on the nervous system and contribute materially to mental and physical fatigue. Such a condition may become detrimental to the health and efficiency of the personnel. The cost of vibration control will generally be recovered in a short time with an actual increase in personnel efficiency thereafter.

The correction of a vibration problem after an installation has been completed is not always simple or economical, and therefore, adequate consideration prior to the installation of machinery or other equipment in motion can often result in considerable saving in time and expenses. A basic knowledge of the theory of vibration and its control permits the plant engineer to predetermine the vibration-control requirements, if any, of a proposed installation and is helpful also in dealing with vibration problems already in existence.

Control of mechanical vibration is a specialized branch of engineering, and many texts and papers have been written on the subject. A bibliography of such material will be found at the end of this section. A brief explanation of the theory and application of the principles of vibration control is given in the following pages.

Definition of Vibration Terminology in Common Use. *Vibration* is a periodic motion in alternately opposite directions from the position of equilibrium of a machine, machine element, or other mass.

Periodic motion is a motion which repeats itself in all its characteristics at definite intervals of time or periods of vibration.

Free vibration is the harmonic motion of a body elastically supported after being displaced from its position of rest and released.

Forced vibration is the periodic vibration of an elastically supported system being acted upon by an external periodic force.

Steady state is a continuous repetition of a vibration cycle after an elastic system has been acted upon by a system of forces for sufficient length of time.

Transient state is the change in the vibratory motion of the system due to the application of changing external forces.

Natural frequency is the number of vibrations or cycles per unit of time that a freely vibrating body will undergo.

Forced frequency or disturbing frequency is the number of vibrations or cycles per unit of time which a body undergoes owing to the external forces acting upon it.

Frequency ratio is the ratio of forced frequency to natural frequency.

Resonance is the state reached when an elastically supported system is acted upon by an external force having the same frequency as the natural frequency of the system, resulting in increasing amplitudes of the system and increasing forces transmitted by the system.

Beats. When two vibrations of slightly different frequencies act upon a common system, the vibrations will at times add, increasing the amplitude of vibrations, and at other times cancel each other, reducing the amplitude of vibrations, and these increases and decreases in amplitude result in periodic beats.

Critical speed is a speed at which the disturbing frequency equals or is close to the natural frequency of the part or system, resulting in a resonant condition.

Amplitude is the maximum distance or displacement of a vibrating body from a neutral or mean position.

Damping is the introduction of friction into a vibrating system.

Isolation efficiency is the percentage of reduction of a disturbing force transmitted to a supporting structure.

Static conditions are conditions dealing with bodies at rest.

Dynamic conditions are conditions dealing with bodies in motion.

Vibration Instruments. The need for vibration instruments in solving a vibration problem depends a great deal on the nature of the disturbance and the factors to be determined in order to make an intelligent analysis of the problem. In the case of a disturbance caused by what might be considered as practically a simple harmonic motion, such as a single-cylinder vertical engine or compressor so balanced that the horizontal forces are very small in comparison to the vertical, conducting a vibration test would not be necessary since all the principal characteristics of the machine are known before the installation is made. The disturbing frequency will be equal to the constant speed of operation. The primary unbalanced force along the cylinder center line can easily be determined from the equation $F = (W/g)\omega^2e$

where W = weight of reciprocating parts, lb
g = acceleration of gravity (32.2 ft/sec^2)
ω = angular frequency, radians/sec
e = one-half stroke, in.

All the unbalanced forces and moments, both primary and secondary, for machinery such as reciprocating compressors, pumps, and engines can usually be obtained directly from the equipment manufacturer. With this information, plus the total weight of the equipment, the center of gravity, and over-all dimensions, the necessary calculations can be made to arrive at the solution to the problem of isolating the machine.

In many pieces of equipment, however, the disturbance may be caused by a combination of two or more simple harmonic vibrations or a combination of various types of vibrations, making it practically impossible to determine by calculation the characteristics of the disturbance resulting from the combination of all the various forces acting within the machine. In such cases the resulting characteristics of the disturbing vibration can be obtained through the use of vibration instruments.

The instruments most generally used for this type of work can be broken down into three general categories: (1) frequency measuring, (2) vibration measuring, and (3) acceleration measuring.

Frequency-measuring Instruments. Instruments used for determining disturbing frequencies in a system are nearly all based on the principle of resonance. The simpler types of instruments are known as tachometers and are useful for determining frequencies below about 6,000 cycles per min. They are in two general types. One contains a single adjustment reed which can be easily lengthened or shortened to correspond to the frequencies within its range by simply turning a knob. The other type, known as the Frahms tachometer, consists of a box containing several reeds, each having a slightly higher natural frequency than the next. With either type of instrument, the maximum amplitude of vibrating reed determines the disturbing frequency. At this point, a condition of resonance exists between the disturbing frequency and the natural frequency of the instrument. Where the frequency varies rapidly over a wide range, it becomes difficult to follow the changing frequency with this type of instrument. In most practical problems, however, it is sufficient to determine the lowest disturbing frequency in the system, and this can readily be found by use of the above instrument. Where it is necessary to have a complete knowledge of a complicated vibration wave shape, a recording instrument is used which produces a graphic record of the wave on a paper or film, thus permitting a detailed analysis. Another type of frequency-measuring instrument known as the stroboscope works on the principle by which the frequency of a flashing light thrown on a moving body is varied until it is in synchronization with the frequency of the body at which point the body appears to stand still.

Vibration-measuring Instruments. Vibration-measuring instruments are used for determining the amplitude of a vibration. A "seismic" instrument known as a vibrometer is ordinarily used for this purpose. It consists of a mass mounted on relatively soft springs inside a box.

The instrument is fastened or firmly held to the vibrating machine, and the ratio between the relative amplitude of the machine and the suspended weight within the instrument is observed. When the disturbing frequency is close to the natural frequency of the instrument, the relative amplitude observed will be large, and in order to determine the actual amplitude of motion of the vibrating machine, it will be necessary first to determine the disturbing frequency. Where the ratio between the disturbing frequency and the natural frequency of the instrument is large, the relative amplitude will be small, and the mass of the instrument will tend to stand still in space. The relative amplitude observed for high-frequency ratios, at least 2:1 or greater, can, for the most practical purposes, be considered equal to the actual amplitude of motion of the machine. In such cases, the instruments can be used for determining amplitude directly without taking into consideration the frequency. There are many types of amplitude meters or vibrometers intended for very rugged use such as might be expected in power plants, machine shops, and industry in general. They are easily read and are quite accurate, especially when used with high-speed machinery.

A more elaborate form of vibrometer containing a recording mechanism is known as a vibrograph. This instrument is often equipped with a timing device, and in operation, the relative amplitude is recorded on a moving strip of paper or film. This strip travels through the instrument at a constant known speed. The strip is marked with a standard timing wave or timing notches for the instrument. By comparison between the standard timing curve and the inscribed vibration curve, it is possible to determine both the frequency and amplitude of the vibrating machine.

Acceleration-measuring Instruments. It was pointed out that, in the case of vibrometers and vibrographs, accurate direct reading of amplitude can be made only where the disturbing frequency is high compared with the natural frequency of the instrument and that such a machine will increase in accuracy as the speed of the machine or disturbing frequency increases. Damping is therefore not necessary since the possibility of resonance does not exist. Instruments for measuring acceleration are designed on the opposite side of the resonant curve. Accelerometers are built somewhat similar to a vibrometer with the exception that stiff rather than soft springs are used for suspending the mass within the instrument. The object here is to have the natural frequency of the instrument higher than the disturbing frequency. For very small frequency ratios, the acceleration can be found directly by measuring the indicated amplitude and multiplying it by the square of the natural frequency of the instrument. Hence, for an impure vibration containing higher harmonics, the instrument will be subject to higher frequency than the one for which the acceleration is desired. It is therefore very possible to obtain a resonant condition, which, of course, is undesirable. Accelerometers are, therefore, generally constructed with a high degree of damping so as to prevent resonance and reduce the effect of the higher harmonics.

Theory of Vibration Control. By careful study and analysis, it is often possible to determine the cause of vibration and reduce it at its source by means of balancing. It is, of course, necessary to balance the machine both statically and dynamically in order to effect any appreciable amount of vibration reduction. Since it is impossible to balance completely any machine in operation, a certain amount of vibration is to be expected. The relative cost of balancing a machine to the point where the disturbing vibration is reduced to a tolerable amount, compared with the cost of isolation, is a determining factor in deciding the steps to be taken for correcting the problem. It usually develops that the cost of providing isolation is much less than the cost of eliminating the cause.

Efficient isolation is in general provided for by mounting the equipment in question on a resilient material having a natural frequency lower than the disturbing frequency.

The disturbing frequency is generally known and often equal to the speed of the machine, or it can be determined through the use of frequency-measuring instruments. The natural frequency of the isolating material is largely dependent upon the static deflection of the material due to the weight which it carries. The curve of Fig. 31-1 shows the relationship between static deflection and natural frequency and applies to all materials where the damping factor is small.

The equation of the curve of Fig. 31-1 based on an undamped single degree of freedom is

$$\omega_N = \sqrt{g/\delta_{st}} \qquad \text{radians/sec}$$

or

$$f_N = 3.14\sqrt{k/W} = 3.13\sqrt{1/\delta_{st}} \qquad \text{cps}$$

$$f_N = 188\sqrt{1/\delta_{st}} \qquad \text{cycles/min}$$

If viscous damping is introduced into the system by means of a dashpot or the equivalent, the equation becomes

$$\omega_{N(\text{damped})} = \sqrt{1 - (C/C_c)^2}\,\omega_N \qquad \text{radians/sec}$$

$$f_{N(\text{damped})} = \sqrt{1 - (C/C_c)^2}\,f_N \qquad \text{cps}$$

It can be seen from this curve that, for cases where it is required to provide a natural frequency in the isolation material of 100 cycles per min, a static deflection of approximately 3½ in. is required. While it is possible to obtain this large deflection with various types of material such as cork or rubber, it would be necessary to provide a considerable thickness of material for this purpose. Steel coil springs, on the other hand, can be designed for this deflection or even greater deflection without involving the use of an excessive amount of material. In general, steel-spring mountings are used where the required static deflection range from about ³⁄₁₀ to about 5 in., and for special cases, even a larger deflection can be provided. Fabricated rubber mountings are generally intended for small static deflections, usually not exceeding approximately ¼ in., although some rubber mountings are capable of providing as much as ½-in.

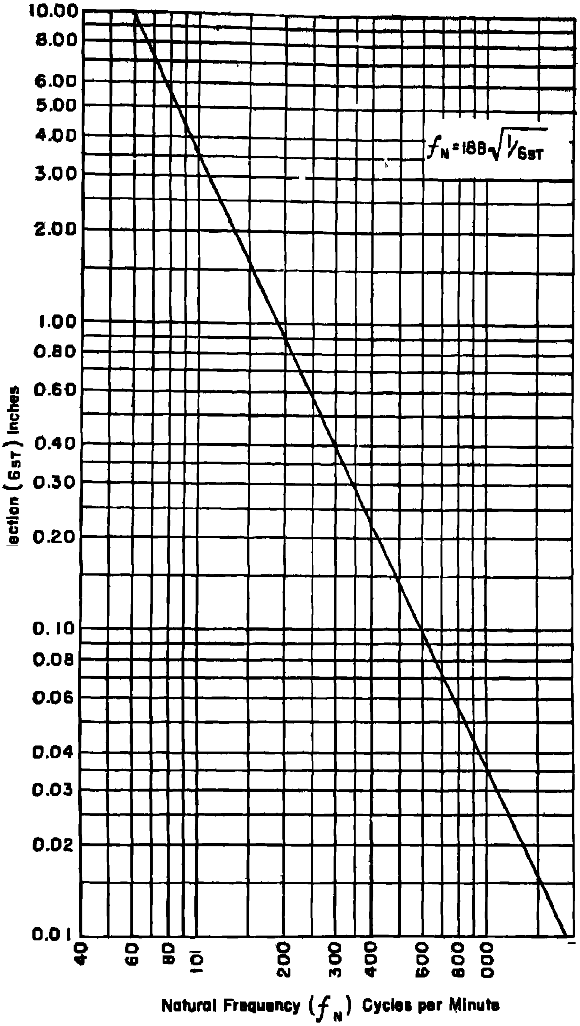

Fig. 31-1. Deflection-frequency relationship for undamped systems.

deflection. The static deflection provided through the use of cork is for the most part dependent upon the thickness of material that can be practically and economically employed. This would also hold true for the case of solid rubber applied in sheets under a foundation or machine and for other sheet material similarly employed.

The usual application is for cases where the static deflection required does not exceed about $\frac{3}{10}$ in.

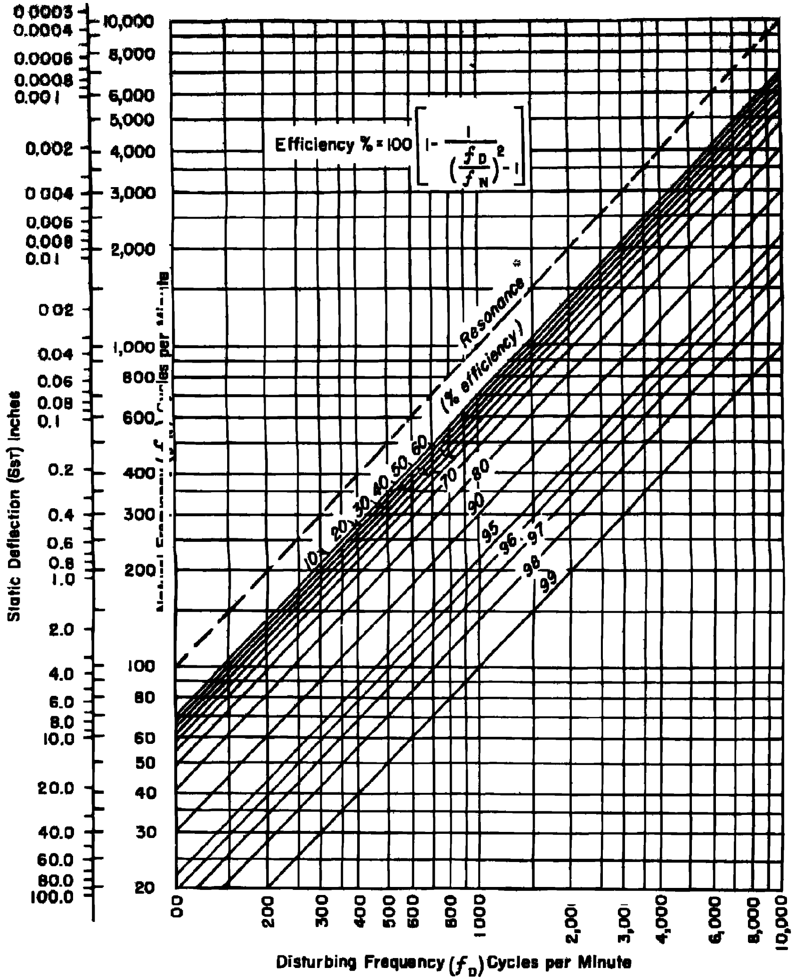

FIG. 31-2. Vibration isolation efficiencies for various natural and disturbing frequencies in undamped systems.

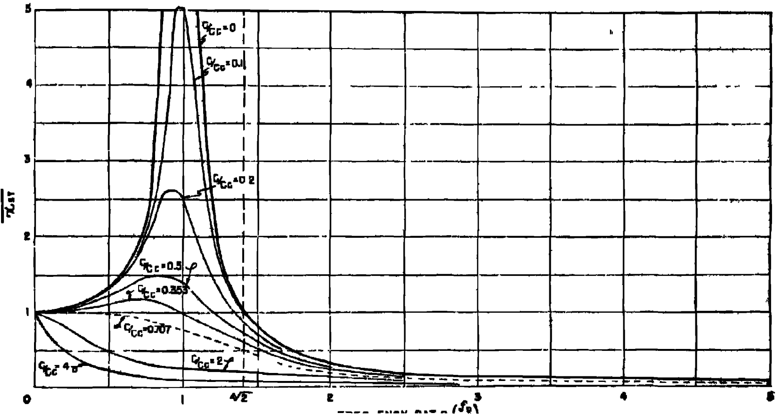
With the disturbing frequency of vibration and the natural frequency of the isolation material known, the expected isolation efficiency can be obtained directly from the curve of Fig. 31-2 or from the equation

$$\text{Efficiency, per cent} = 100\left[1 - \frac{1}{(f_D/f_N)^2 - 1}\right]$$

EXAMPLE: A machine operates with a disturbing frequency of 564 cycles per min, the vibrations being vertical and harmonic. A spring support is placed under the machine and undergoes a 1-in deflection because of the dead weight of the machine. The natural frequency of the support is therefore 188 cycles per min (from Fig. 31-1). Assuming zero damping in the system when operating continuously at a constant speed, find the efficiency of isolation.

$$\text{Efficiency, per cent} = 100\left[1 - \frac{1}{(564/188)^2 - 1}\right] = 87.5$$

The intersection of the vertical lines of disturbing frequency with the horizontal lines of static deflection or natural frequency of the isolation material gives the per cent of isolation efficiency. The curve is actually a representation of the ratio of the force transmitted to a supporting structure to that of the force created by the machine. The curve holds true for cases of vibration systems with little or no damping and for frequency ratios above $1\frac{1}{2}:1$.



SPEED CONSTANT—SPRING VARIES

FIG. 31-3. Damping effect on relative magnification factor for various frequency ratios.

In all cases where vibration isolation is considered necessary, the primary function of the isolation system is to reduce the forces transmitted to a minimum. There are many cases, however, where, in addition to reducing the forces, it is also of great importance for a machine to operate with a minimum amount of movement or relatively small amplitude. This is especially true for cases such as compressors, pumps, engines, and similar installations where piping-system connections leading from the isolated equipment are involved. Continuous vibrations of large amplitude would, of course, be detrimental to the piping system and would result in repeated piping failures. Accordingly, flexible connections should be employed in the pipe lines whenever possible. Through the use of proper isolation and sufficient inertia mass the amplitude of the system can be made small and the possibility of piping failures greatly reduced.

Constant-speed Machines. The curves of Fig. 31-3 will illustrate the effect of damping on the relative amplitude of vibration for an isolated system where the operating speed of the machine remains constant while the natural frequency of the spring is varied. The heavy line of the curve represents a system in which there is no damping ($C/C_c = 0$) and is derived from the equation for relative amplitude:

$$\frac{X}{x_{st}} \quad \frac{1}{(f_D/f_N)^2 - 1}$$

The amplitude of the system is

$$X = \frac{F}{k[(f_D/f_N)^2 - 1]} \text{ for } \frac{f_D}{f_N} > 1$$

$$X = x_{st} = F/k \text{ for } \frac{f_D}{f_N} = 1$$

$$X = \frac{F}{k[1 - (f_D/f_N)^2]} \text{ for } \frac{f_D}{f_N} < 1$$

This undamped curve is seen to start out at a point where the frequency ratio equals zero and the amplitude of the system is equal to the spring deflection due to the static action of the shaking force. As the frequency ratio approaches one, the relative amplitude climbs rapidly until a point is reached where the disturbing frequency is equal to the natural frequency of the system, and resonance occurs. If the system were allowed to operate at this point, the resilient support would compress solid or extend beyond its capacity, and the system would soon break down. As the frequency ratio increases above one, the curve is seen to drop rapidly until, at a point where the ratio is equal to $\sqrt{2}$, the relative amplitude again becomes equal to unity. Further increase of the frequency ratio causes a gradual decline and reduction in the relative amplitude, approaching zero as the frequency approaches infinity. The relative amplitude obtained at a frequency ratio of 2:1 and higher is generally considered satisfactory for most types of industrial and power-plant equipment.

The effect of viscous damping on the system is illustrated by the curves falling under the undamped curve. It can be seen that increasing the damping factor results in a decrease in the relative amplitude for small frequency ratios and is especially effective at or near the point of resonance. As the frequency ratio increases above resonance, however, the effect of damping in the reduction of relative amplitude is greatly diminished, and at frequency ratios of 2:1 and above, the damping curves are very close to the undamped curve, indicating that damping beyond this point is practically ineffective in reducing relative amplitude.

The amplitude of the damped system is given by the equation

$$X = \frac{F}{k\sqrt{[(f_D/f_N)^2 - 1]^2 + 4(C/C_c)^2(f_D/f_N)^2}}$$

The curves of Fig. 31-4 are based on the same conditions as those of Fig. 31-3, except that here the relationship is between frequency ratio and the ratio of the force transmitted to that of the shaking force. This force ratio is generally referred to as transmissibility.

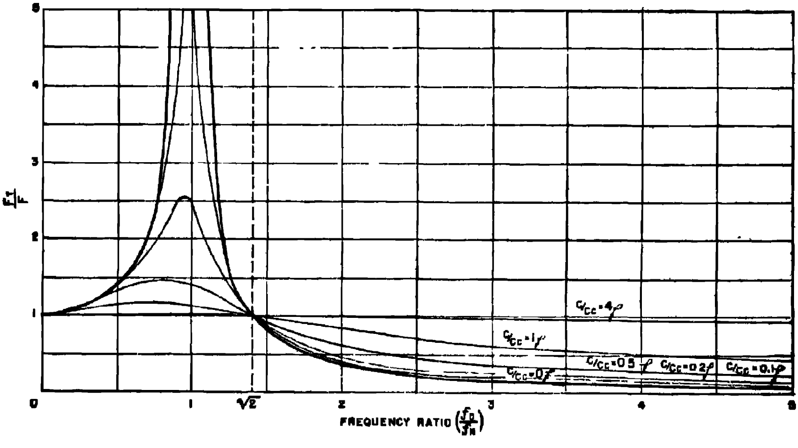
Here again the heavy curve indicates a system in which there is no damping. The transmissibility is seen to start out at unity where the frequency ratio is zero, corresponding to a machine mounted on a solid foundation. A transmissibility of one at this point indicates that all the unbalanced force created by the equipment is transmitted undiminished to the supporting structure. As the frequency ratio increases, the curve rises rapidly until, at the point of resonance, frequency ratio = 1, the force transmitted would be infinitely great, and allowing a machine to operate at this point would lead to its destruction. A further increase in the frequency ratio causes a rapid decrease in the transmissibility until again a point is reached where the force transmitted is equal to the shaking force at a frequency ratio equal to $\sqrt{2}$. Beyond this point, the curve gradually drops, approaching zero at a point where the frequency ratio approaches infinity. Frequency ratios of 2:1 and higher are generally considered satisfactory from the standpoint of reduction in the forces transmitted to the supporting structure. This ratio would correspond to approximately 66⅔ per cent reduction in force. The actual amount of reduction required will, of course, depend upon the construction of the supporting structure and the amount of vibrating force that it is able to sustain. Slightly higher frequency ratios will give an even greater reduction in force such as a ratio of 3:1, corresponding to a force reduction of 87½ per cent.

This undamped force ratio can be calculated from the equation

$$\frac{F_T}{F} = \frac{1}{\left(\frac{f_D}{f_N}\right)^2 - 1} \text{ for } \frac{f_D}{f_N} > 1$$

$$\frac{F_T}{F} = \frac{1}{1 - \left(\frac{f_D}{f_N}\right)^2} \text{ for } \frac{f_D}{f_N} < 1$$

The light lines falling under the undamped curve for frequency ratios below the $\sqrt{2}$ and above the undamped curve for ratios above the $\sqrt{2}$ indicate that viscous damping is effective only in reducing transmitted forces for the lower ratios, while its presence actually increases the forces transmitted above those in an undamped system for higher frequency ratios.



SPEED CONSTANT — SPRING VARIES

FIG. 31-4. Damping effect on relative transmissibility for various frequency ratios.

The transmissibility for the damped system is

$$\frac{F_T}{F} = \sqrt{\frac{1 + 4\left(\frac{C}{C_c}\right)^2\left(\frac{f_D}{f_N}\right)^2}{\left[1 - \left(\frac{f_D}{f_N}\right)^2\right]^2 + 4\left(\frac{C}{C_c}\right)^2\left(\frac{f_D}{f_N}\right)^2}}$$

Since the major portion of industrial and power-plant machinery is designed for constant-speed operation or sometimes two-speed operation, an elastic system of mounting will, when properly designed and selected for the particular installation, provide a highly efficient method of mounting both from the standpoint of reduction in amplitude and reduction in transmitted forces. A small amount of damping is beneficial, however, especially for machinery which is slow in reaching its operating speed. While approaching this speed, the system will have to pass through resonance, and if the increase in speed is slow, there is the possibility of creating excessive amplitudes and transmitted forces in the region of resonance. A small amount of damping will limit these undesirable conditions and yet will have no noticeable effect on the system under normal operation.

Example: A machine having a total weight of 4,000 lb is mounted directly on a set of four spring units located at the corners of the base. The spring constant of the combined springs is 29,400 lb per in. A viscous damping device is placed between the machine and the support and has a damping factor of 0.2. The system is vibrated by a vertical reciprocating part in the machine which weighs 100 lb and oscillates harmonically at a frequency of 1,000 cycles/min through a 4-in. stroke. Find the amplitude of the system and the force transmitted to the supporting structure.

The natural frequency of the system is

$$f_{N(\text{damped})} = \sqrt{1 - (C/C_c)^2}\, f_N = \sqrt{1 - (0.2)^2}\, f_N = 0.982\, f_N$$

and the natural frequency of the springs without damping is

$$f_N = 188\sqrt{k/W} = 188\sqrt{29{,}400/4{,}000} = 510 \quad \text{cycles/min}$$

then

$$f_{N(\text{damped})} = 0.982 \times 510 = 500 \quad \text{cycles/min}$$

The force created by the reciprocating weight is

$$F = \frac{w}{g}\omega^2 e = \frac{w}{g}(2\pi f)^2 e = \frac{100}{386}\left(\frac{2\pi 1{,}000}{60}\right)^2 \times 2 = 5{,}680 \text{ lb}$$

and the amplitude of the system is

$$X = \frac{F}{k\sqrt{\left[\left(\frac{f_D}{f_N}\right)^2 - 1\right]^2 + 4\left(\frac{C}{C_c}\right)^2\left(\frac{f_D}{f_N}\right)^2}} = \frac{5{,}680}{29{,}400\sqrt{\left[\left(\frac{1{,}000}{500}\right)^2 - 1\right]^2 + 4(0.2)^2\left(\frac{1{,}000}{500}\right)^2}} = 0.0645''$$

The force transmitted is

$$F_T = F\sqrt{\frac{1 + 4\left(\frac{C}{C_c}\right)^2\left(\frac{f_D}{f_N}\right)^2}{\left[\left(\frac{f_D}{f_N}\right)^2 - 1\right]^2 + 4\left(\frac{C}{C_c}\right)^2\left(\frac{f_D}{f_N}\right)^2}}$$

$$F_T = 5{,}680\sqrt{\frac{1 + 4(0.2)^2\left(\frac{1{,}000}{500}\right)^2}{\left[\left(\frac{1{,}000}{500}\right)^2 - 1\right]^2 + 4(0.2)^2\left(\frac{1{,}000}{500}\right)^2}} = 2{,}350 \text{ lb}$$

Variable-speed Machinery. There are other types of machinery less frequently encountered in industrial and power-plant installations which normally operate over a wide range of variable speed. Figures 31-5 and 31-6 show the relationship of absolute amplitude and transmissibility to frequency ratio for such installations where the speed or disturbing frequency varies while the frequency of the supporting system remains constant.

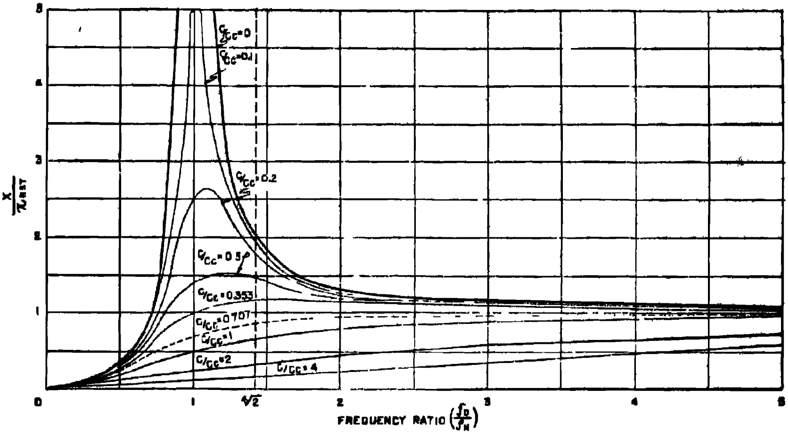
In Fig. 31-5 it is seen that all curves, regardless of the damping factor, start out at zero absolute amplitude and zero frequency ratio, indicating that, where there is no speed, there will, of course, be no amplitude. As the speed or forced frequency increases, the undamped curve rises rapidly, and when the frequency ratio reaches unity, resonance occurs. Increasing the speed of the machine above this point results in a reduction in amplitude in a manner similar to that shown in Fig. 31-3, except that here the curve is seen to approach unity as the disturbing frequency approaches infinity. Instead of indicating relative amplitudes, as in Fig. 31-3, the curve shows the relationship of absolute amplitudes. For any given frequency ratio occurring below the point of resonance, the absolute amplitude of the undamped curve of Fig. 31-5 will be the relative value given for Fig. 31-3 minus 1. For frequency ratios above 1, the values given in Fig. 31-3 plus 1 will correspond to the absolute value of Fig. 31-5.

This curve for zero damping follows the relationship

$$\frac{X}{x_{st}} = \frac{1}{[1/(f_D/f_N)^2] - 1}$$

and the amplitude becomes $X = \dfrac{F_N}{k\left[\dfrac{1}{(f_D/f_N)^2 - 1}\right]}$

where $F_N = (w/g)\omega_N{}^2e$



SPRING CONSTANT— SPEED VARIES

Fig. 31-5 Damping effect on absolute magnification factor for various frequency ratios.

By introducing damping into the system the equation becomes

$$\frac{X}{x_{st}} = \frac{1}{\sqrt{\left[\dfrac{1}{\left(\dfrac{f_D}{f_N}\right)^2} - 1\right]^2 + 4\dfrac{\left(\dfrac{C}{C_c}\right)^2}{\left(\dfrac{f_D}{f_N}\right)^2}}}$$

$$X = \frac{F_N}{k\sqrt{\left[\dfrac{1}{\left(\dfrac{f_D}{f_N}\right)^2} - 1\right] + 4\dfrac{\left(\dfrac{C}{C_c}\right)^2}{\left(\dfrac{f_D}{f_N}\right)^2}}}$$

Damping is seen to be effective in reducing the absolute magnification of the amplitude at all frequency ratios and might, therefore, be considered beneficial from this standpoint alone. It does, however, have a very undesirable effect on the transmitted forces as shown in Fig 31-6.

In Fig 31-6, the undamped curve starts at zero, absolute transmissibility when the machine is at rest. As the speed of the machine increases, the curve rises to infinity at a point of resonance, drops rapidly to a frequency ratio equal to the $\sqrt{2}$, and then gradually reduces to unity as the speed approaches infinity. A high degree of damping is seen to be beneficial for all values of frequency ratios below $\sqrt{2}$ since it greatly reduces the transmitted forces in this region as compared with small amounts of damping or no damping. For speeds resulting in frequency ratios greater than the $\sqrt{2}$, it is seen that damping in any amount is detrimental to the system since it results in a considerable increase in the transmitted force.

The equation for the undamped system is

$$\frac{F_T}{F_N} = \frac{1}{[1/(f_D/f_N)^2] - 1}$$

and with viscous damping

$$\frac{F_T}{F_N} = \sqrt{\frac{1 + 4\left(\frac{C}{C_c}\right)^2\left(\frac{f_D}{f_N}\right)^2}{\left[\frac{1}{\left(\frac{f_D}{f_N}\right)^2} - 1\right]^2 + 4\frac{\left(\frac{C}{C_c}\right)^2}{\left(\frac{f_D}{f_N}\right)^2}}}$$

Practical Application. *Reciprocating Engines and Machines.* Reciprocating engines, pumps, and compressors in the single- or multicylinder types are used extensively throughout the power and industrial field. The extent of vibration-control precautions to be used in the mounting of such equipment depends to a large extent upon the unbalanced forces which the machine will create. It is possible in many cases to balance the machine by the addition of counterweights to the rotating parts and thus arrive at an acceptable solution to the vibration problems. Nevertheless, since a machine can never be perfectly balanced, forces causing vibrations will always exist.

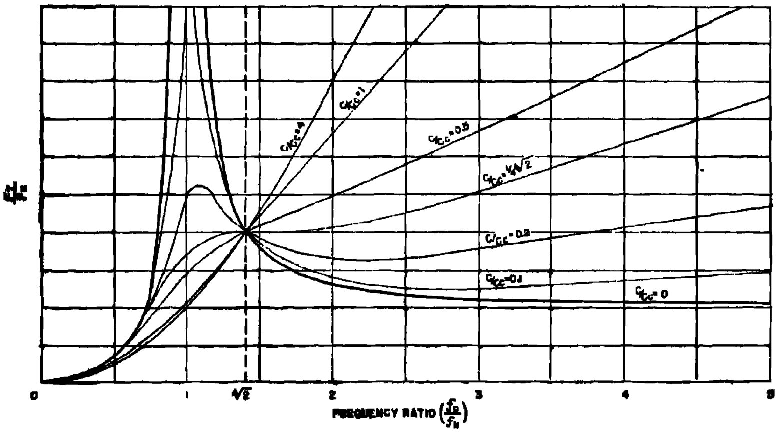


Fig. 31-6. Damping effect on absolute transmissibility for various frequency ratios.

Table 31-1 will be found useful, at least for the purpose of comparison in judging the type of unbalance to be expected from reciprocating machines of various number of cylinders and crank arrangements.

The forces and couples usually considered are primary, occurring once per revolution, and secondary, occurring twice per revolution, and are caused by the inertia of the rotating and reciprocating weights. The forces and moments are calculated from the weight of the reciprocating parts w_1, the weight of the rotating parts w_2, the speed of the machine ω, the crank radius e, the length of connecting rod l and the center-line distance between cylinders d. The primary forces acting along the axis of the cylinder

NOTE: O = forces cancel out, U = moment unbalanced.

(F_{p1}) for a single-cylinder engine are given by the equation

$$F_{p1} = [(w_1 + w_2)\omega^2 e]/g$$

and the secondary forces (F_{s1})

$$F_{s1} = w_1\omega^2 e/g$$

The primary forces (F_{p2}) acting perpendicular to the axis of the cylinder are

$$F_{p2} = w_2\omega^2 e/gd$$

and the secondary forces

$$F_{s2} = 0$$

The cases given in Table 31-1 are representative of some of the more frequent cylinder arrangements, and it can be seen that, for all engines shown, except the six- and eight-cylinder units, there will exist unbalanced forces or couples. The couples are the result of unbalanced forces acting simultaneously in opposite directions and not along the same line.

Effective vibration control has been provided for all sizes of reciprocating engines from small fractional-horsepower single-cylinder units to the very large multicylinder diesel generator plants. The six- and eight-cylinder units can generally be mounted directly on isolators, although a concrete foundation is usually inserted between the engine and the isolation. The operating speed must be taken into consideration in all cases, and particularly for engines having unbalanced characteristics. Large diesel electric plants operating at speeds as low as 250 rpm have been isolated by means of coil springs and a concrete foundation to such a high degree of efficiency that their operation could not be felt or picked up by sensitive testing equipment anywhere in the vicinity of the installation.

The use of the concrete foundation as an inertia mass is not a necessity from the standpoint of reducing the transmission of unbalanced forces to the substructure, but it is very advantageous in reducing the amplitude of vibration. An effective installation must reduce the transmission of vibration to a satisfactory minimum and at the same time provide stability.

Figure 31-7 illustrates a foundation design widely used for the isolation of large engines, pumps, compressors, and other types of reciprocating machines.

Figure 31-8 is an illustration of isolation applied directly under the base of a small reciprocating compressor. The unit is supported on coil springs within the isolator housing, and lateral motion as well as vertical oscillation is limited through the use of adjustable chocks also located within the isolator housing.

The combination of coil-spring mountings and concrete foundation provides high isolation efficiencies and extremely small amplitudes. A mechanical dry-friction type of damping device is often used in conjunction with the spring mountings to limit excessive motion when the equipment is started up and passes through resonance or when loads are suddenly changed. The usual capacity range for this type of isolation mounting is from 5,000 to 35,000 lb.

Cork is also widely used for this same type of equipment and provides very effective isolation if properly applied. At a loading of about 2,000 psf, which is generally considered a safe and efficient stress for the more widely used materials, cork will deflect approximately 5 per cent of its thickness. It is evident, therefore, that for slow-speed unbalanced machines where large deflections are required for high efficiencies, excessive thicknesses of cork may be required. In such cases a compact spring unit will be found more practical and less expensive.

Rotating Equipment. Machinery designed for rotational operation is generally very well balanced statically and dynamically. This is especially true of high-speed rotational machines. Included under this type of equipment are centrifugal compressors, pumps, turbines, blowers, exhausters, and electric motors. Other types of rotational equipment which are well balanced initially but become unbalanced in use through uneven distribution of the material being handled or an uneven deposit of scale or other solids are rotating mills, pulverizers, crushers, hoggers, extractors, centrifuges, washers, and similar equipment.

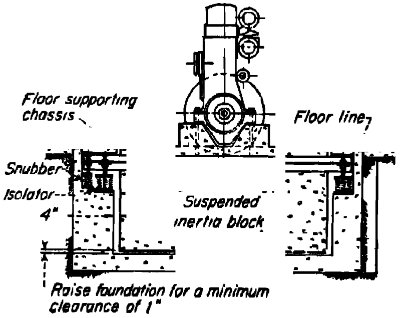

FIG. 31-7. Spring-isolated concrete foundation used for mounting large engines, compressors, and similar equipment. (*Courtesy Korfund Co., Inc.*)

Vibration will be created by all such equipment regardless of how well it is balanced. The high-speed machines, which are generally extremely well balanced for the protection of the machine parts themselves, do not usually cause a severe mechanical disturbance, and the vibrations transmitted are usually in the sound range. These high-frequency vibrations can nevertheless be very troublesome since they may be transmitted over a considerable distance to neighboring plants and dwellings. A remote structure or any of its parts, if in resonance with the vibration, may be forced to vibrate excessively while there may be no apparent vibration in the immediate vicinity of the machine.

Isolation applied at the source can prevent vibration from traveling any further. There have been many occurrences where a so-called perfectly balanced machine has vibrated a building so violently that its operation was prohibited simply because the supporting structure, even though very heavily constructed, happened to have a natural frequency equal to or close to the disturbing frequency of the machine. Isolation in one form or another will usually provide an economical assurance of vibration control. The type of isolation material and method of application are dependent upon the characteristics of the machine and the conditions under which it is to be installed.

Impact Machinery. This type of equipment has not been covered in the theoretical application of this article since it does not involve vibration in the same sense as

does rotating and reciprocating machinery. Machines operating primarily on the principle of impact, however, are to be found in many types of plant and industry and are often a cause of serious disturbance.

In the case of heavy impact machinery, the determination of the type of resilient mounting, size of foundation, and other factors requires individual study and thorough analysis because of the many variable factors involved. Complex equations have been derived and tested whereby the action of such an installation can be accurately predetermined. In general, a most efficient impact-machine installation is made by suspending the machine and its concrete foundation on spring isolators as illustrated in Fig. 31-9. In this type of suspension a sufficient amount of concrete is used to act as an inertia mass which will limit vertical motion of the block under maximum impact to a predetermined amount considered satisfactory for the operation of the particular machine involved. The spring mountings then absorb shock, changing its form to that of a more slowly applied force to the outside structure. In many cases where actual tests have been conducted with large forging hammers in operation, it is impossible to obtain any indication of shock or vibration transmission from the hammer to the adjacent pit wall or surrounding structure.

SECTION A-A

Fig. 31-9. Typical spring-isolated hammer foundation. (*Courtesy Korfund Co., Inc.*)

An advantage of the adjustable-spring-type method of mounting is the ability to level the hammer at any time in case of possible uneven settlement of the outer concrete pit, which is impossible if an unisolated hammer foundation settles. This adjustment can be made at any time without taking the hammer out of operation simply by making a few extra turns on the isolator adjustment bolts.

Figure 31-10 illustrates the effect of various isolating materials on the amplitude of the foundation and the force transmitted to the substructure for a particular hammer installation. If the hammer were mounted on a very rigid support, practically all the hammer's energy except that portion used in deforming the work would be transmitted, causing severe shock disturbances. Hammer anvils are generally mounted with several layers of timber separating the concrete foundation from the anvil. The timbers will deflect slightly under impact, resulting in a slight reduction of shock transmission, but usually the reduction is not sufficient to prevent the shock transmission to other parts of the building. Soil conditions have a very important influence on shock transmission from an unisolated hammer.

FIG. 31-10. Efficiency of various isolating materials based on hammer with 65,000 ft-lb blow energy. Total weight of hammer and foundation, 715 tons. (*Courtesy Korfund Co., Inc.*)

It can be seen from Fig. 31-10 that, for increasing thickness of sheet-isolation materials placed under the foundation, a small reduction of force transmitted to the subsoil results, and where steel springs are used, a very great reduction is obtained. The motion of the foundation after impact is largest for the spring installation because of its greater resiliency, but this can be reduced to any desired amount by the addition of weight to the system without necessarily increasing transmission. It might appear as though an isolated hammer installation would reduce the efficiency of the machine because of the movement of the foundation after impact. This, however, is not the case since the timbers usually incorporated with an unisolated hammer are practically eliminated except for a thin protective layer between the anvil and the concrete. Thus the foundation becomes a part of the anvil, offering even greater reaction to hammer ram.

Certain types of presses require isolation in the same manner as described above for hammers. In general, however, a press usually has sufficient inertia mass in its own frame so that a concrete foundation is not required to obtain operating stability and efficient shock control.

Impact machinery used in the metal-forming industry, such as punch presses, shears, and brakes, can be efficiently isolated even on an upper story of a building by use of properly designed spring-type of mountings. In some cases where the height of the machine is large in comparison to the area of its base, an extended structural-steel or other type of base covering a greater floor area than occupied by the machine itself may be required in order to provide the necessary machine stability as well as to spread the weight over a sufficient floor area to fall within allowable static-load limitations.

Machine Tools. Machine tools can either be the cause of vibration disturbance, or they may have to be protected against external vibration. The effect of vibration on the latter type of machine tools, such as grinders, jig borers, etc., can result in costly work spoilage and damage to the machine. In most cases there are many sources of vibration disturbance and shock with a resulting wide variation in disturbing frequency. It is therefore usually necessary to provide an isolation material with a large static deflection to isolate against low steady-state vibration as well as intermittent shock. Owing to the large deflection requirements of the isolation material, it is usually necessary to incorporate a spring-type mounting to obtain a practical design.

Machine tools which are often a source of vibration, such as broaching machines, milling machines, shapers, and planers, can be located close to precision machines and sensitive laboratory equipment without fear of vibration disturbance if properly isolated. Cork and rubber mountings have been used under this type of equipment with considerable success, but here also, as in practically all cases, the type of structure upon which the equipment is mounted is an important factor. A vibration-creating machine tool mounted on a 2- or 3-in. thickness of cork located in a sturdy reinforced-concrete building can usually be expected to operate without the slightest vibration disturbance, while the same machine mounted in the same manner in a wood-frame-constructed building might be the cause of a great deal of vibration disturbance. In the case of the latter installation a comparatively soft spring mounting or a combination spring-and-rubber mounting may be required for high isolating efficiency.

Laboratory Equipment. It is often found advantageous to locate sensitive testing equipment and precision measuring devices in a locality where vibration disturbance from an outside source is to be expected. The setup may be of a temporary nature or a portable unit, and it would therefore be impractical to attempt to eliminate the source of vibration. On the other hand, the installation may be of a permanent nature, located in a plant having many sources of vibration, or even a single source of vibration, where the expense of isolating the disturbance at its source may be unwarranted.

In these cases it is desirable to isolate the sensitive equipment against the possibility of incoming vibration. Owing to the many variables involved in an installation of this type, it is almost always necessary to design a special type of mounting to suit the equipment under consideration. Generally speaking, it is usually necessary to provide considerable spring deflection in order to isolate against many vibration frequencies as well as shocks.

NOISE SILENCING

There is little need to emphasize the growing importance of sound insulation and acoustical treatment to reduce the noise level in buildings. The need for a quiet atmosphere in hospitals, schools, libraries, and other public buildings has been long felt, and special precautions are generally taken to eliminate noise from these structures. More recently noise elimination has been carried into offices because tests have shown that subjection to noise decreases workers' efficiency and promotes fatigue. For instance, a metabolism experiment made in an eastern university showed that typists used 19 per cent less energy and gained slightly more than 4 per cent in typing speed when the noise intensity was reduced 50 per cent. Similar tests in industry indicate that noisy factory conditions promote fatigue, decrease worker efficiency, and lead to accidents as well as physical and mental sickness.

General Theory. Sound results from stimulation of the auditory nerves by wave energy set in motion by a vibrating body and transmitted through an elastic medium (usually air) to the ear.

The two most important characteristics of a sound are its frequency and intensity.

Frequency, the simpler of the two, is the number of vibrations per unit of time experienced by the sound source. This controls the "pitch" of the sound. For example, a "middle-C" musical tuning fork vibrates at a frequency of 264 cps, and one octave higher corresponds to a vibration of 528 cps. The audible frequency range is from about 20 to 20,000 cps. The approximate frequency range for the male voice is from 80 to 465 cps, while the female range is from 195 to 1,045.

Frequency has a great effect upon sound intensity and is also an important factor in locating the source of disturbing noises.

Sound intensity is defined as the energy transmitted per unit of time through a unit area taken perpendicular to the path of the sound wave. The amplitude of vibration of any membrane (including the eardrum) upon which a sound wave impinges is proportional to the sound intensity, which, in turn, is proportional to the square of the product of the amplitude and frequency of the vibration.

Sound intensity also varies as the square of the pressure created by the sound wave, and this principle is widely used in sound-intensity meters. The ear is sensitive to a minimum root-mean-square pressure variation of 0.001 dynes per sq cm, assigned a relative value of 1. The maximum pressure variation the ear can endure without pain is 1,000 dynes per sq cm or a relative value of $1{,}000/0.0001 = 10^7$. The unit of proportional intensity in the first case would then be $1^2 = 1$, and the proportional intensity in the second would be $(10^7)^2 = 10^{14}$.

Since an individual's sensitivity to sound is roughly proportional to the logarithm of the intensity, a system was devised where intensity is measured in units equal to ten times the logarithm of the proportional intensity as shown in Table 31-2. The unit is called the decibel.

Table 31-2

Pressure variation, dynes/sq cm rms pressure	Relative pressure	Proportional intensity	Intensity, db
0.0001	1	$(1)^2 = 1$	$10 \log_{10} 1 = 0$
0.001	10	$(10)^2 = 10^2$	$10 \log_{10} 10^2 = 20$
0.01	10^2	$(10^2)^2 = 10^4$	$10 \log_{10} 10^4 = 40$
0.1	10^3	10^6	60
1.0	10^4	10^8	80
10.0	10^5	10^{10}	100
100.0	10^6	10^{12}	120
1000.0	10^7	10^{14}	140

However, as indicated in Table 31-2, the physical reaction to sound is only roughly proportional to the intensity in decibels. As the intensity increases, the ear becomes less sensitive, and sounds of lower frequency do not produce so great an audible effect on the eardrum as higher frequency sounds. The "loudness scale" shown in Fig. 31-11 resulted from tests on thousands of people to determine the actual average reaction to sound intensity.

Since sound-measuring instruments give an intensity reading in decibels, for practical purposes the curve shown in Fig. 31-11 is very helpful in converting these readings to loudness units.

Example: Suppose vibration isolation and acoustical treatment in a factory had resulted in a decrease in the loudness intensity (as read by the instrument) from 80 to 70 db. What was the actual physiological per cent reduction in loudness?

Solution: 80 db corresponds to 17,000 units on the loudness scale (Fig. 31-11) and 70 db to 8,000. This then represents a 53 per cent reduction in actual loudness.

Table 31-3 shows the results of tests in buildings to determine the amount of noise present. The "observed" effect of an external noise entering a room is dependent upon the amount of noise normally encountered in a room. For example, the noise effect produced by dropping a book in a library is much greater than when the same

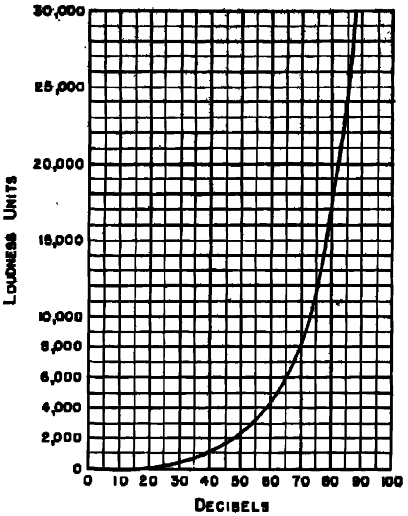

FIG. 31-11. This loudness-unit-decibel curve gives the average physiological reaction of the human ear to different sound intensities.

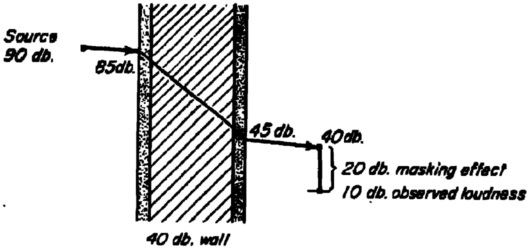

FIG. 31-12. Wall and sound source showing effect of typical sound-intensity losses and masking upon final observed loudness.

Table 31-3. Noise in Buildings*

Location and source	Level above threshold of hearing, db
(Painful noise level)	130
Boiler factory	97
Subway, local station with express train passing	95
Noisy factories	85
Very loud radio in home	80
Stenographic room, large office	70
Average of six factories	68
Information booth, large railway station	57
Noisy office or department store	57
Moderate restaurant clatter	50
Average office	47
Noises measured in residence	45
Very quiet radio in home	40
Quiet office	37
Quietest nonresidential location	33
Average residence	32
Quietest residence measured	22

book is dropped in a busy office because the normal office noise "masks" a portion of the additional sound. This is further illustrated in Fig. 31-12.

Sound transmission into and through buildings results from three phenomena:

1. Air-borne sounds transmitted from room to room through doors, windows, cracks, through air-conditioning duct-work, etc.
2. Structural-borne sounds transmitted through building materials in contact with each other
3. "Diaphragm-transmitted" sounds resulting from sound waves impinging upon a wall, door, etc., and inducing a vibration in the material which then sets up sound waves on the other side of the diaphragm

FIG. 31-13. Methods for reducing air-borne noise transmission.

Air-borne Noise. Control of air-borne noise is extremely important and is often the limiting factor in a noise-control program. For example, a door or window may transmit more noise than the entire wall, thus making it impractical to improve the wall insulation if nothing can be done about the openings.

The smallest cracks around pipes passing through a wall, poorly fitting doors, and other almost unnoticeable openings may destroy the sound insulation value of a wall. Figure 31-13 shows a few of the many practical solutions which have been devised for preventing air-borne noise transmission. It is sometimes possible to use shields of sound-absorbing material around the noise source. The use of double doors and windows is very effective, and a double sound door can easily be incorporated into an existing structure as shown in Fig. 31-13. Special soundproof windows are now available which permit a flow of air through the window.

Noise transmission through ventilating systems is very common. The noise due to mechanical vibration of the fan and motor is easily isolated from the system by using a short length of flexible duct in the line at the fan outlet. Lining the ducts with absorbent material is very effective in preventing "air-rush" noises, and this can be accomplished without materially increasing the frictional resistance if a thin layer of perforated sheet metal is used on top of the absorber. The most effective single point for lining ventilating ductwork is at the inlet end.

In some factories the use of acoustical materials on the ceiling and walls will be found effective in reducing the noise level within the room. A discussion of the theory of acoustics is beyond the scope of this section, but most manufacturers of acoustical materials are prepared to analyze the noise conditions in a plant and recommend the proper acoustical treatment.

Structural-borne Noise. Structural-borne noise is encountered in all types of buildings, but particularly in modern concrete and steel buildings where contacting members afford an excellent path for sound transmission. It is not uncommon for noise to travel through steel building columns and be extremely objectionable half a dozen floors from the source, without even being noticeable on floors closer to the source. This occurs when a portion of the building structure at some distant point happens to have a natural frequency corresponding to the frequency of the disturbing vibration, which results in great amplification of the induced vibration.

Structural-borne noise and mechanical vibration are practically synonymous since mechanical vibrations transmitted through the structure and activating some portion of the building also have exactly the same effect as described above. Consequently, vibration isolation of offending machines often provides a solution to the problem of structural-borne noise. When noise carried to other parts of the building is known to be a factor, it is usually possible to incorporate organic materials in the vibration isolator to dampen the noise, as discussed elsewhere in this section.

Since structural-borne noise results from sounds passing from one building member to another, it follows logically that breaking up the path of propagation will usually result in improved conditions. The value of vibration isolators is partially due to this factor, and this principle is utilized extensively in "floating" floors and "hanging" ceilings which will be discussed under Floor and Ceiling Structures.

Where one part of the building is to house equipment creating vibration and noise and another part of the structure must be particularly noise free, a complete separation approximately ½ in. wide is sometimes provided between the two parts. Separate building-column footings are used, and where there is a possibility of vibration transmission through the soil between the footings (particularly in wet ground, clay, or rock), it is frequently desirable to provide isolation materials under the columns of the building housing the offending machines.

Diaphragm-transmitted Sounds. Sound transmission of the diaphragm type is very common; every wall, ceiling, floor, door, etc., is a membrane which may be induced to vibrate by sound waves impinging upon one side, thereby transmitting the wave motion to the air on the opposite side of the membrane. The amount of energy transmitted through a membrane depends upon:

1. The energy of the sound wave striking the membrane, since it is this energy which sets the structure vibrating and maintains the vibration.

2. The mass of the membrane, since more energy is expended in vibrating a heavy membrane than a light one.

3. The stiffness of the membrane, because the stiffer the structure, the smaller is its amplitude of vibration and consequently the smaller the amplitude of the sound waves induced on the other side.

4. How the edges of the membrane are held in position, particularly as this affects the damping of the membrane. This consideration is of much more importance on small rather than large membranes.

5. The natural frequency of the membrane, which is of importance only if resonance is encountered—when the frequency of the impinging waves is equal to the natural frequency of the panel, in which case the amplitude of induced vibration may become very great.

Consideration of the above conditions suggests many practical design limitations and practices which can greatly affect the sound insulation value of a structure. These will be discussed further under Wall Structures.

Wall Structures. Sound transmission through walls can be the result of air, structural, or diaphragm noise propagation. The following are a few of the most important fundamental principles (in addition to those previously given) which influence wall design:

1. The sound-insulation value of a homogeneous wall is primarily dependent upon its weight-per-unit area and varies as the logarithm of this factor. For this reason, it is seldom practical to resort only to greater wall thicknesses for improved insulation.

2. For the same weight-per-unit area, a nonhomogeneous membrane consisting of two or more layers is a better sound insulator than a homogeneous membrane. This type of construction offers a great deal of resistance to diaphragm transmission, and the general use of furring strips or other separators between the layers reduces the path of propagation for structural-borne noise (see constructions shown in Fig. 31-14).

3. The empty air space between layers of a nonhomogeneous wall is frequently a better sound insulator than filler materials sometimes used in such spaces, particularly if the wall layers are connected in any way.

4. However, the complexity of a nonhomogeneous structure is not necessarily an accurate index of its efficiency, from either the standpoint of sound transmission or cost, and each design should be checked against existing standard constructions of known insulation value.

5. Wall structures generally absorb greater proportions of high-pitched than low-frequency noise, as shown in Table 31-4. Furthermore, various constructions are better for different frequencies, and it is often possible to choose the type of wall best suited for isolation of particular known noises within a definite frequency range. It should also be noted that the intelligibility of voices depends upon the high-pitched tones. This means that it is frequently possible to eliminate completely the transmission of voice sounds or to reduce them to an unintelligible murmur by absorbing the higher frequency tones.

6. Increasing the insulation value of the walls of a room is effective only against transmission of noises from an external source into the room. Acoustical treatment must be used to reduce the noise level due to sounds originating within the room. On the other hand, the use of both acoustical materials and sound-insulation walls can be very effective in isolating the noise source.

Some of the more common types of wall structures are shown in Fig. 31-14 and described in Table 31-4. Of the very many types tested and reported on in the U.S. Department of Commerce bulletin, "Building Materials and Structures," by V. L. Chrisler, only a few of the best and most practical or most interesting are shown in Fig. 31-14. However, a study of the values for some of these panels is enlightening in view of the principles outlined above.

Comparison of panels 86 and 66 shows the advantage of providing several separated layers in a wall, but it will be noted that in panel 71, where this principle has been combined with the advantages of rigidity and mass provided by a heavier wall, the results are even better.

Two methods of improving the insulation value of basic panel 148 are shown in panels 149 and 150, where the path of propagation is reduced by using large-headed nails driven between the sheets of lath instead of through them and by further breaking up the sound path with spring clips. The same effect can be seen by comparing panel 175 with panels 164 and 165, where an improvement in insulation value is obtained by staggering the studs to prevent solid contact between both sides of the wall.

The value of eliminating rigid connections between the two wall surfaces is shown very well in panel 138, where an increase of approximately 40 per cent in insulation value is obtained over panel 161 by separating the two surfaces with spring clips.

A comparison of panels 63, 64, and 65 seems to indicate that little is sacrificed in sound insulation where it is necessary to use harder burned wall tile in order to support greater loads.

The value of a double-wall construction is clearly shown by comparing panels 159 and 160E, where an increase of approximately 50 per cent results from the use of a double wall. Increasing the distance between the double walls by 122 per cent increases the insulation value approximately 7½ per cent as shown in panel 160A.

The great increase in sound insulation obtainable by "floating" a wall with furring strips or spring clips makes this one of the best methods for improving an existing wall structure. This principle is used extensively where a "room within a room" is constructed to insulate an existing room.

Floor and Ceiling Structures. Sound transmission through floors and ceilings can result from air, diaphragm, or structural-borne noise. The last is the principal source of difficulty, since it is usually possible to correct air-borne noise and because the heavier construction of floors and ceilings reduces considerably the diaphragm transmission.

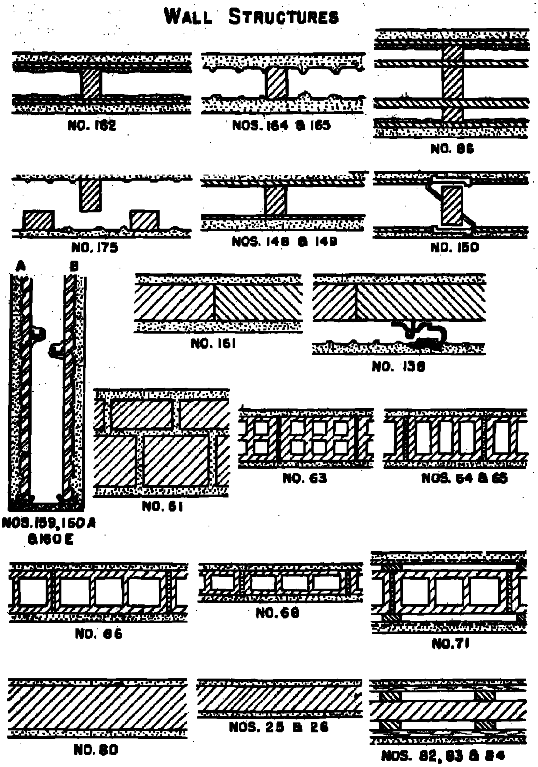

FIG. 31-14. Typical wall structures (see Table 31-4).

In industrial applications, it should be remembered that the noise due to mechanical-equipment vibration is the most readily transmissible of all types of noise and is much worse in the room below the machine than in the room above. Many companies locate their offices on the ground floor of a building and their production equipment on the floors above. The result is far more disturbing noise in the offices than there would be had the offices been located above the machinery. Furthermore, the usually heavier construction of the lower building floors makes them better suited for carrying machinery than the upper floors, which are better suited for offices, laboratories, etc.

The almost universal panacea for noise and vibration transmission through floors and ceilings is the employment of a resilient support under the offending machine.

Panel description:

25—4-in. brick panel; plastered both sides with brown coat of lime plaster; smooth, white finish

26—4-in. brick panel, plastered both sides with brown coat of gypsum plaster; smooth finish

61—Hollow clay-tile panel (two units, 3¾ × 5 × 12 in. and 8 × 5 × 12 in.) side construction; plastered both sides with brown coat gypsum plaster; smooth, white finish

63—6 × 6 × 12-in. hollow clay load-bearing partition tile, six cells; plastered on both sides with brown coat gypsum plaster; smooth, white finish

64—Same as No. 63, except medium-burned three-cell tile

65—Same as No. 63 except soft three-cell partition tile

66—4 × 12 × 12 in. hollow clay three-cell partition tile; brown coat gypsum plaster both sides; smooth, white finish

68—Same as No. 66, except 3 × 12 × 12-in tile

71—4 × 12 × 12-in. hollow clay three-cell partition tile; wood furring strips; paper; metal lath: scratch and brown coats gypsum plaster; smooth, white finish

80—8-in. New Hampshire brick panel; brown coat gypsum plaster both sides; smooth, white finish

82—New Hampshire brick laid on edge; furring strips wired; gypsum plaster board; scratch and brown coats gypsum plaster both sides; smooth, white finish

83—Same as No. 82, except furring strips nailed instead of wired

84—New Hampshire brick laid on edge, furring strips nailed; ½-in. Insulite; scratch and brown coats gypsum plaster both sides; smooth, white finish

86—Wood studs; ½-in. Flaxlinum nailed to each side of 1 × 2-in. furring strips; wood lath, scratch and brown coats gypsum plaster both sides; smooth, white finish

138—3 × 12 × 30-in. gypsum tile, U.S. Gypsum resilient clip; metal lath and gypsum plaster on one side; gypsum plaster applied directly to tile on other side; smooth, white finish both sides

148—Wood studs; gypsum lath nailed to studs, nails approximately 6 in. apart; scratch and brown coats sanded gypsum plaster; smooth, white finish; thickness of plaster ½ in.

149—Same as No. 148, except lath held on with special large-head nails driven between sheets of lath

150—Same as No. 148, except lath attached to studs with spring clips instead of nails

159—Panel A only—Metal studs of ¾-in. channel iron expanded metal lath; scratch and brown coats gypsum plaster; smooth, white finish, applied to one side only

160A—Two panels similar to panel No. 159 placed back to back and resting on 1-in.-thick cork; 10-in. distance from face to face of panels

160E—Same as No. 160A, except 4½-in. distance from face to face

161—3 × 12 × 30-in. gypsum tile; brown coat gypsum plaster; smooth, white finish

162—Wood studs; wood lath; scratch and brown coats lime plaster; smooth, white finish

164—Wood studs; metal lath; scratch and brown coats lime plaster; smooth, white finish

165—Same as No. 164, except gypsum plaster used

175—Wood studs staggered; expanded metal lath; scratch and brown coats gypsum plaster; smooth, white finish; thickness of grounds ¾ in.

* From CHRISLER, V. L., *Building Materials and Structures*, National Bureau of Standards.

The most effective way of isolating machines is the use of vibration and sound isolators between the machine and the floor as discussed in another portion of this section. This also has the advantage of isolating each machine against vibration from the other machines. Many companies have all their vibration-creating machines mounted on "floating" bases.

In cases where individual machine isolation is impractical, as for example, when trucks are moving around on the floor and possibly picking up and dropping loads, a "floating" floor is very effective in reducing vibration and noise transmission. In fact, for sound-insulation purposes, a floating floor under the disturbing equipment is much more effective than a hanging ceiling on the room below.

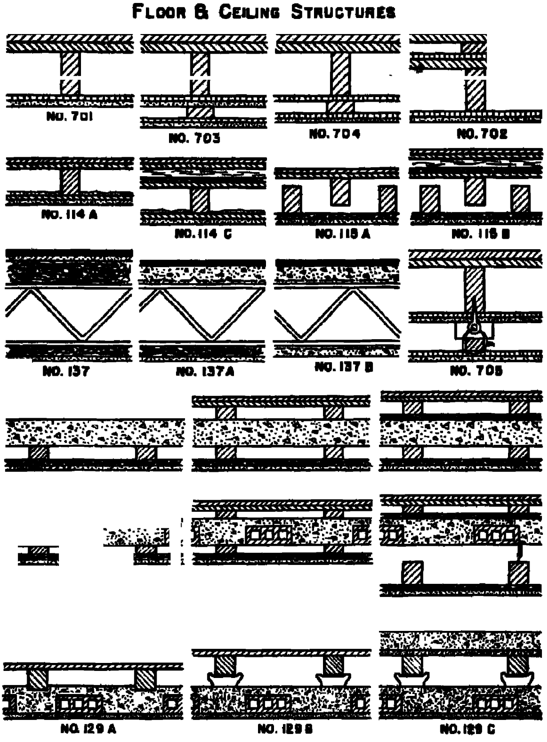

FIG. 31-15. Typical floor and ceiling structures (see Table 31-5).

Figure 31-15 and Table 31-5 illustrate some typical primary floor and ceiling structures and indicate what can be done to improve them by adding secondary floating floors and ceilings.

Considerable caution should be exercised when floating floors are considered for use under impact machinery which may also be supported on vibration mountings. It is very easy to destroy completely the effectiveness of shock mountings by placing them on a floor which is so resilient that it "gives" before the mountings have a chance to deflect and absorb the impact. This will result in vibration and noise transmission into both the floating floor and the main building structure. Generally speaking, if a floating floor is used to absorb the vibration and noise from mobile vibration-creating equipment, the isolation mountings under any stationary impact-creating equipment should be placed on the primary floor, with the secondary floating floor cut out around the machine to assure that the mountings have the most rigid support.

Panel description:

114A—Floor panel; wood joists; plaster on wood lath on lower side; subfloor and ⅜-in. finish floor upper side

114C—Same as 114A, except flooring; rough flooring; ½-in. Insulite; floating floor, consisting of nailing strips, rough, and finish flooring

115A—Suspended ceiling; wood joists; ½-in. Insulite plaster ceiling; rough floor; finish floor; ends of ceiling and floor joists nailed to common support

115B—Same as 115A, except flooring; rough floor; ½-in. Insulite; floating floor consisting of 1 × 2-in. nailing strips, rough flooring, and ⅜-in. oak finish flooring

116A—Reinforced concrete flat-slab-type floor construction; Insulite furred out and applied as ceiling; brown coat gypsum plaster; smooth, white finish

116B—Same as 116A, except for addition of floor consisting of 1 × 2-in. nailing strips, rough flooring, and ⅜-in. oak finish flooring

116C—Same as 116B, except ½-in. Insulite added between concrete slab and floating floor

117A—Combination floor panel constructed of 4 × 12 × 12-in. three-cell partition tile; ceiling finished with furring strips, ½-in. Insulite, and plaster

117B—Same as 117A, except for addition of floating floor, consisting of 1 × 2-in. nailing strips, rough flooring, and ⅜-in. oak finish flooring

118—Same as 117B, except ½-in. Insulite added between masonary slab and floating floor; ceiling stripped off and suspended ceiling attached by means of wires

129A—Combination floor panel constructed of 4 × 12 × 12-in. three-cell partition tile; ceiling finished with ½-in. brown coat gypsum and smooth white finish coat; floor of 13/16-in. oak flooring, nailed to 2 × 2-in. nailing strips on 16-in. centers grouted into concrete

129B—Same as 129A, except U.S. Gypsum resilient clips used between concrete and nailing strips

129C—Same as 129B, except oak flooring removed, and ½-in. gypsum plasterboard attached to the nailing strips and ½-in. Hydrocal applied on top of the plasterboard

137—Floor panel constructed of 8-in. Mac Mar joist, with 3-in. Thermax clipped on top and 1-in. Thermax clipped on bottom joist; ½-in. concrete poured on top of the 3-in. Thermax; floor finished with ¼-in. battleship linoleum cemented on top of concrete; ceiling finished with brown coat of gypsum plaster and a smooth white finish coat

137A—Same as 137, except 3-in. Thermax removed and standard high-rib metal lath attached to top of joist; 2½-in. concrete poured on top of lath; battleship linoleum cemented to top of concrete

137B—Same as 137A, except ceiling of panel 137A removed and standard high-rib metal lath attached to underside of joist; scratch and brown coats gypsum plaster; smooth, white finish

701—2 × 8-in. joists; ½-in. fiberboard lath and ½-in. gypsum-plaster ceiling; 1-in. pine subflooring and 1-in. pine finish flooring.

702—Same joists and ceiling as 701; 1-in. pine subfloor; ½-in. fiberboard, 1 × 3-in. sleepers, and 1-in. pine finish floor

703—Same as 701, except a second ½-in. fiberboard and ½-in. plaster ceiling added to the existing ceiling of 701 by means of 1 × 3-in. furring strips

704—Same joists and floor as 701, except ceiling consisted of ½-in. fiberboard, 1 × 3-in. furring strips, ½-in. fiberboard lath, and ½-in. plaster face

705—2 × 8-in. joists, 16-in. o.c., 1-in. pine subfloor, 1-in. pine finish floor; 1 ceiling consisting of ½-in. plaster on ½-in. fiberboard lath next to joists; an additional plaster and fiberboard lath ceiling on 2 × 2-in. joists suspended by screw eyes and wire loops 36 in. o.c., 4-in. below upper ceiling, 5 × 5 × 2-in. fiberboard-block pads at fastenings

INDUSTRIAL CONTAINERS AND PACKAGING EQUIPMENT

BY P. P. KENNEDY, M.E.

Container Consultant, E. I. du Pont de Nemours & Co., Inc.

INTRODUCTION

The past 20 years have seen a tremendous growth in the science of economic preparation, packaging, and transportation of commodities produced by American industry. During the last decade with the impetus afforded by the Second World War, industrial packaging and packing have matured to the extent that a new profession has been born—packaging engineer. Today, a packaging engineer must know the chemical and physical properties of construction materials used in containers, the economic and functional basis of container design, the adaptability of containers to plant handling facilities and methods of transportation, and the customers' methods of handling and merchandising. In addition, the packaging engineer must know the optimum equipment to fill, seal, label, and pack the many different types of containers with an almost innumerable number of commodities, each having its own particular peculiarities.

Accordingly, it is impossible to state in a handbook the most efficient container or piece of packaging equipment to use for all commodities. It is hoped that the description and comments following will result in a better understanding of certain basic principles whereby the selection and design of containers and related equipment may be improved.

The containers and equipment covered in this section will pertain to the so-called "industrial" type. Small packages usually for retail trade constitute another complex field of the "package engineer." Readers whose interests lie in that field are referred to the "Modern Packaging Encyclopedia," published by the Packaging Catalogue Corporation, for information on small containers and allied weighing, filling, checkweighing, sealing, etc., equipment.

Inasmuch as the following is at best a generalization, it is suggested that shippers acquaint themselves with the packaging requirements and container specifications in the Consolidated Freight Classification and Agent H. A. Campbell's Freight Tariff No. 4, publishing the Interstate Commerce Commission Regulations for the Transportation of Explosives and Other Dangerous Articles by Freight including Specifications for Shipping Containers. Further, detailed container data may be obtained through procurement of a number of Federal Specifications listed on page 1901.

BAGS

Multiwall Paper Bags. Multiwall paper bags, as their name implies, are bags consisting of three to six plies of paper (two-ply bags are referred to as duplex bags). Each ply of paper may have a basis weight (weight per 500 sheets 24 by 36 in.) of from 40 to 70 lb if made of plain kraft paper. Frequently, one or more plies of a multiwall bag will consist of an asphalt-laminated sheet (two sheets of paper laminated with asphalt; a laminated sheet counts as one ply), asphalt- or wax-impregnated sheet, or other specially treated or laminated sheets to provide additional protection against moisture absorption, to provide greaseproofness, wet strength, heat resistance, etc.

The types of multiwall paper bags are described by the construction of the top and bottom of the bags. They are

1. Sewn open mouth (SOM) (see Fig. 32-1*a*)
2. Sewn valve (SV) (see Fig. 32-1*b*)

3. Pasted open mouth (POM) (see Fig. 32-1c)
4. Pasted valve (PV) (see Fig. 32-1d)

Several kinds of valves may be procured, although two are in common use. They are the plain valve and the valve with tuck-in sleeve. The latter is used where siftproofness is required or moisture absorption by the contents is to be avoided. The tuck-in sleeve is extra paper and requires an extra manufacturing operation and so costs more than the plain valve.

Sewn-bottom bags are nominally constructed with gussets and pasted bags without gussets (see Fig. 32-1). However, several bag manufacturers have installed equipment permitting the manufacture of gusseted pasted bags. The presence of gussets lends filled bags to more stable stacking and better appearance, and the gussets afford an excellent display surface for advertising copy when bags are stacked flat. It should be understood that gussets are not mandatory in a sewn-bottom bag. Nongusseted or flat bags are frequently specified when bags are of very heavy construction and no sifting of contents through the closure can be permitted. The use of a flat bag in such instances halves the amount of paper which the needle must penetrate, and the bag is of uniform thickness throughout its width.

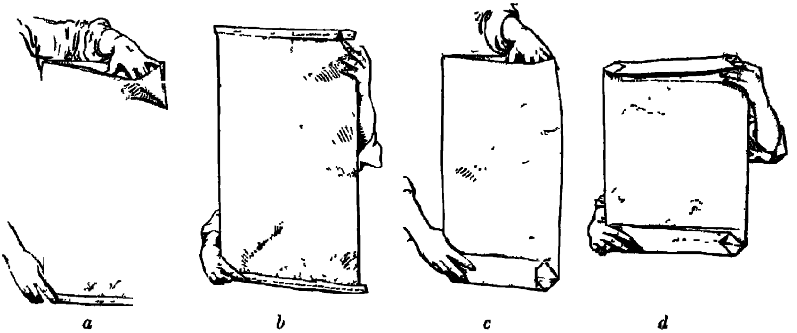

Fig 32-1. Types of multiwall paper bags.

Multiwall paper bags are of sizes and constructions to meet the trade demands. Maximum and minimum sizes will vary with various bag producers, but it is generally understood that bags ranging in capacity from 0 3 to 7.5 cu ft may be obtained. The proper size of bag to hold a specific amount of a given material must be determined by trial. However, Table 32-1 gives paper width and length dimensions for various capacities of bags from which bag sizes may be computed. Bag sizes arrived at by use of Table 32-1 are for sewn open-mouth bags. Methods of converting such bags to pasted or valve bags are given in explanation notes with Table 32-1. In choosing a bag size it should be borne in mind that an ideal bag for handling and stacking is one *which when filled* and lying flat has a length equal to twice the width and depth 30 to 40 per cent of the width. Generally not over 100 lb of product should be shipped in a paper bag.

The construction, *i.e.*, number and basis weight of plies, of a multiwall paper bag will depend upon (1) density of product, (2) net weight, (3) product characteristics, (4) content protection required, (5) value of contents, and (6) method of transportation. No set rule can be established for determining bag construction. Experience is the only teacher. With a range in bag strength from 120 lb of paper (3 plies of 40-lb paper) to 360 lb (6 lb of 60-lb paper) and the capacity range mentioned above, a wide variation is possible. Several important factors in determining bag construction should be remembered:

1. The larger the bag, the more strength required.
2. The heavier the net weight, the more strength required.
3. Products of relatively high value ($0.50 to $1.00 per lb) deserve more protection than cheaper products.

Example Determine bag size for bag to hold 100 lb of product weighing 35 lb per cu ft From table go down column of product density to 35 lb per cu ft and go horizontally to various bag lengths listed Arbitrarily choose a bag length say 45 in for which a paper roll width of 49 in is indicated Subtract 1 in from roll width for longitudinal bag seam (49 − 1 = 48), divide remainder by 2 (48 = 24) Flat bag will be 24 by 45 in For gusseted bag arbitrarily choose gusset size (2½ to 5 in) For this example say gusset of 4 in Bag size then becomes 20 by 4 by 45 in

To determine bag sizes for other than 100 lb of material use cubic foot capacity column for base point

To convert sewn-open-mouth sewn closure bag to pasted bottom bag sewn closure, assume sewn-open-mouth bag 18 by 3 by 36 in

Deduct from length ½ in gusset width—1½ in.
Deduct from length ½ in for sewing— ½ in
2 in

$$36 - 2 = 34 \text{ in}$$

Add to tube length one-half width of bottom plus 1¼ in. Assume 5 in wide bottom—$\frac{1}{2} \times 5 + 1\frac{1}{4} = 3\frac{3}{4}$ in

$$34 + 3\tfrac{3}{4} = 37\tfrac{3}{4}$$

Pasted bag size—21 by 37¾ in.

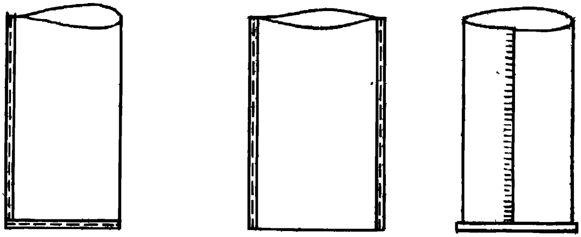
4. Less-than-carload and less-than-truckload shipments demand containers of greater strength than carload or truckload.

For new users of paper bags it is recommended that complete facts be given the bag supplier and his recommendations be followed by shipping tests in order to assure proper bag construction.

A new type of multiwall paper bag consisting of three or more plies of finely creped paper with all plies loosely adhered with asphalt, latex, or some similar adhesive is now manufactured. While the creping requires additional paper compared to a plain multiwall bag and extra manufacturing operations result, it is said that less paper strength is required, owing to the creping which permits the bag to stretch when subjected to rough handling. In addition, the creped paper gives excellent stack stability.

Textile Bags. Textile bags are commonly limited to burlap and cotton and usually require a paper liner either attached to the fabric or entirely separate and inserted in the bag prior to filling.

Textile bags are made in a wide variety of sizes and grades or strengths of fabric. Burlap is specified on the basis of weight per yard of 40-in.-wide goods; *i.e.*, 8-oz burlap means 36 in. of 40-in.-wide burlap weighs 8 oz. Burlap shipping bags are normally made of burlap weighing from 7½ to 12 oz. Cotton or osnaburg shipping bags are specified on the basis of yards of a given width of material weighing 1 lb, or the number of ounces 1 yd of a specified width will weigh; *i.e.*, 2.25–36-in. osnaburg means 2.25 yd of 36-in.-wide material weighs 1 lb, or 40-in.–7-oz means 1 yd of 40-in.-wide material weighs 7 oz.



Sewn one side and bottom

Sewn two sides seamless bottom

Cemented center seam, taped bottom

Fig. 32-2.

Textile bags are always of a flat (nongusseted) construction. However, the seams will vary depending upon the protection desired for the bag contents and/or the size of the bag relative to the width of goods from which the bags are to be made. Various types and locations of seams for plain textile and waterproof-paper-lined (WPPL) textile bags are illustrated in Fig. 32-2.

Both burlap and osnaburg bags have high tensile strength in either direction of the fabric and high tear resistance. Accordingly, weights up to 225 lb are safely shipped in textile bags, although the handling of such heavy bags is cumbersome. Textile bags normally have a relatively high resale or reuse value in comparison to paper bags and for that reason are favored by some industries.

DRUMS

Drums are straight-sided or bilge-type containers of circular cross section and may be fabricated from metals, rubber, wood, fiberboard, or combinations of these materials.

Metal Drums. Metal drums range in size from 5- to 110-gal capacity and in gauge of metal from 28 to 12 gauge (steel). The two broad classifications into which drums are segregated are (1) *tight head*, in which the top and bottom heads are attached to the drum body by welding, double seaming, or a combination of the two, and (2) *open head*, in which construction when the cover is removed the drum opening is the same diameter as the side wall of the drum at the section where the cover is applied.

Tight-head Drums—Liquid Contents (*see Fig.* 32-3). These drums are of either two- or three-piece construction. Two-piece drums are made only in 16 and heavier gauges and are fabricated from two pressed sheets circumferentially welded near the middle of the drum body. Three-piece drums consist of a circular body longitudinally welded with the two heads double-seamed, welded, or double-seamed and welded to the body. When heads are attached by double seaming only, it is necessary that a seaming compound be employed which serves as a gasket in the seam. This compound must be one which is unaffected by the drum contents. For this reason it is important that a drum supplier be advised of the nature of the contents being packed. Drums meant for returnable service or those containing dangerous liquids frequently have chime reinforcements. A chime reinforcement consists of a heavy-gauge steel ring (usually two gauges heavier than the drum body) seamed around the chimes of a drum (see Fig. 32-4). Openings for liquid drums are usually of the screw or cap type and are welded or pressed in place. Welded forged fittings are employed for some drums containing dangerous liquids and for heavy-duty drums. Pressed-in fittings are used for single-trip drums and those used in the lighter returnable-drum service.

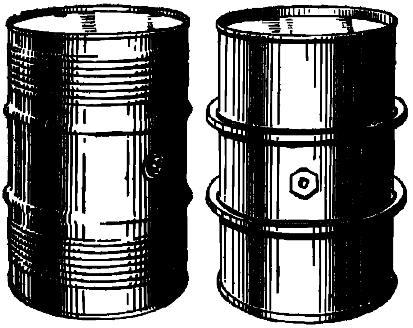


Fig. 32-3. (*Left*) Drum with expanded rolling hoops and corrugations in body. (*Right*) Drum with I-bar rolling hoops.

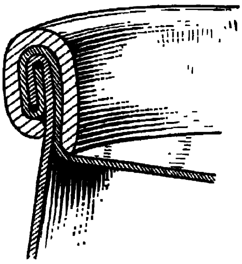

Fig. 32-4. Section of top chime showing double seam and chime reinforcement.

Fittings are available in many types and sizes, but ¾-, 1½-, and 2-in.-diameter fittings are considered standard. Of prime importance in the closure of a drum is the gasket material used between the plug and the flange seat and, in the case of pressed-in fittings, the gasket material between the flange and the body or head of the drum. In effecting a closure, it is necessary to see that the gasket is of proper size and resilience, that it is not twisted, and that the proper amount of torque is applied in tightening the plug. Some types of gaskets and/or closures will not be liquid-tight if too much torque is applied. Drum bodies may be reinforced by rolling hoops and in the case of lighter gauge drums (18 gauge and less) by corrugations in the drum body. I-bar hoops are either 1 by 1½ in. or ¾ by 1¼ in. and are usually fastened to the drum by welding or by swedging. I-bar hoops are employed only on drums of 16 guage and heavier. Swedged hoops are expanded from the drum body and are normally used with drums made of 16-gauge steel or lighter. The so-called light-gauge drums (18 gauge and less) frequently have the sections of the body between the rolling hoops and the head stiffened by corrugations, usually three to five corrugations per drum end with the depth of the corrugations less than the depth of the rolling hoops. Drums for dangerous liquids usually have the heads convex which adds strength to the head and helps to prevent distortion.

Tight-head Drums—Dry Contents. Drums for dry products may be constructed similar to drums for liquids or may have a lock-type of longitudinal seam known as "box" or "Gordon" seams (see Fig. 32-5). These seams are frequently used on drums containing nonhygroscopic products and for products which are molten at time of packing but solidify when cooled. Closures for tight-head drums containing dry products will vary in size from 5 to 16 in. in diameter, but in no instance should they be larger than the head diameter minus 4 in.

Open-head Drums—Dry or Liquid Contents. Open-head drums may be either straight side or bilge type and of two- or three-piece construction. The bodies of the bilge type may be seamless with the bottom head brazed or welded in place, or the body and bottom head may be entirely seamless. The three-piece drums are made in the conventional manner previously described. With open-head drums the top of the body is rolled or curled outward to provide a seat for the cover and to stiffen the body. Closures for open-head drums may be lug type (for small light-gauge drums only), bolted ring seal, or lever-lock ring seal (see Fig. 32-6). Of interest in the open-head-drum picture is a new screw-type closure. This is obtained by a deep drawing of the portion of the cover which is inside the periphery of the body and expanding an "interrupted thread" in several portions of the vertical section of the cover. Similar female threads are expanded in the top side wall of the drum body. Cover closure is made by an approximate 30 deg turn of the cover.

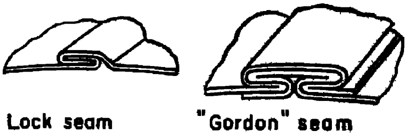

Fig. 32-5.

Although carbon-steel gauges have been used in the foregoing, construction details other than gauge of metal would apply to drums constructed of stainless steel, aluminum, nickel, monel, and other metals.

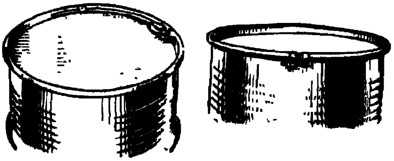

Fig. 32-6. (*Left*) Lever-lock ring. (*Right*) Bolted ring seal.

Of significance at the present time is the widespread interest shown in interior linings for metal drums. Galvanized and tin-dipped drums have long been available, and lacquer-lined drums have been used in the food industry for some years. At present a great deal of work on phenolic- and vinyl-resin-base linings is being done in an effort to produce a satisfactory interior lining which will permit the shipping of acidic and alkaline liquids and solids in carbon-steel drums rather than in more expensive containers.

Rubber-lined Steel Drums. Rubber-lined steel drums with open- and tight-head constructions have been used for many years. The lining is applied to the separate parts of the drum and the parts are then assembled. The tight-head drum is equipped with a special reversible pour-out spout and cap (see Fig. 32-7).

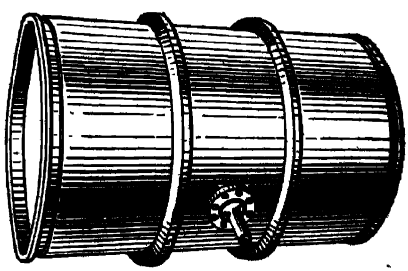

Fig. 32-7. Rubber-lined steel drum with pour-out spout in position.

Fiber Drums. Fiber drums are convolutely wound cylindrical paper shells equipped with fiber, wood, or metal heads. A section of one type of chime construction is shown in Fig. 32-8. These drums have found wide acceptance for shipments of dry and solid products, viscous liquids, and pastes.

Fiber drums are made in sizes ranging from 1- to 75-gal capacity. The majority of capacities are available in two different sizes which permits the nesting of empty drums, thus decreasing freight costs and warehouse space. Because of the wide range of capacities and the variety of products shipped in fiber drums, several strength constructions are available for most of the capacities manufactured. Increase in strength is obtained by adding to the number of plies making up the bodies and heads or by employing higher strength fiberboard. In addition, on some sizes of drums, the bottom chimes are reinforced with a metal hoop. To prevent damage to drums setting on wet platforms, etc., those drums having fiber bottoms are treated. High resistance to moisture-vapor penetration through the fiber is obtained by incorporating in the side wall moisture barriers such as aphalt-impregnated paper, plastic wax, regenerated cellulose, Pliofilm, metal foils, and other moisture-vapor barriers. In the same manner, resistance to chemical attack, fiber contamination, etc., may be obtained by having such a treatment or barrier on the inside facing of the drum. Disks of the same materials are used between the product and the cover to assure complete protection to the contents.

Outside treatments or coatings for fiber drums are also available. Such treatments permit limited exposure to water without deleterious effect to the drum plus enhancing the appearance.

Economically, the fiber drum is competing with light-gauge steel drums, slack barrels, and plywood drums. It merits careful investigation.

Plywood Drums. Plywood drums are straight-sided containers constructed of two or four plies of veneer bonded to each other. The grains of adjacent plies are always at right angles to one another. Although several types of plywood drums have been in general use, a single type is the only one currently being used. This drum is constructed by butting the ends of a plywood sheet and securing the seam by wire stitching a metal strip to the butt seam. Heads are held in place by means of head liners on both sides of the top and bottom heads. These head liners are thin strips of wood, usually elm, which are wire-stitched or stapled to the drum body. The exterior end sections of the drums are reinforced with wood or metal bands which also are stapled. This construction results in a reinforced end or chime, permitting rolling of the drums on their heads, and also keeps the heads of the drums elevated from the floor. Because of the metal stitching of the longitudinal seam, heavy gummed kraft-paper tape is frequently specified to go over the seam on the interior of the drum to afford a smooth interior. It is customary to use a creped-paper drum or barrel liner with plywood drums.

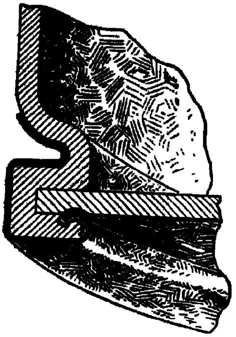

FIG. 32-8. Section view of bottom chime construction of one type of fiber drum. Note the metal chime reinforcement.

Plywood drums are available in sizes of approximately the same capacities as fiber drums. However, it is not customary to make two different sizes of plywood for a given capacity, and nesting of empty drums is not standard practice.

Four-ply veneer drums are used for export shipments and for very heavy loads in domestic service.

BARRELS

Barrels are uniformly bulging side cylindrical-cross-section containers constructed of wood staves bound together with hoops and have flat wood heads of equal diameter. Figure 32-9 illustrates and names the various parts of a barrel. Barrels are classified in two major categories—slack and tight.

Slack barrels are those barrels having parts not sufficiently tight to hold liquids and are therefore used for shipping dry products. Slack barrels are available in capacities from 12 to 64 gal (see Table 32-2 for barrel dimensions and capacities) and in four classifications—commodity, No. 1, mill run, and No. 2.

Commodity barrels are used for heavy loads and are essentially the same as No. 1 with the exception that staves are ½ in. thick, hoops are usually of heavier gauge or wider than those used on No. 1 barrels, and more hoops are employed.

No. 1 barrels are siftproof and are made of No. 1 grade staves and heading. The staves are ⅜ in. thick and tongued and grooved. The heading is ½ or ⅝ in. thick depending on the barrel capacity and the load it is to carry, and heads are single piece, *i.e.*, tongued and grooved and glued or butt-jointed and glued. Content weight up to 600 lb may be shipped in No. 1 barrels provided head liners or cleats are used.

Mill-run barrels are not siftproof and are made of mill-run staves (containing at least 40 per cent of No. 1 staves) and mill-run heading (containing at least 50 per cent of No. 1 pieces). Staves are ¾ in. thick and may be tongued and grooved or butt-jointed as specified. Heading is ½ in. thick and may be made of three to five pieces.

No. 2 barrels are not siftproof and are made of No. 2 staves and heading. Thickness of staves and heading is the same as for mill-run barrels. Generally weights not exceeding 450 lb are shipped in these latter two grades of barrels.

Slack barrels normally have bilge and head hoops of steel, although the commodity barrels are equipped with quarter hoops owing to the heavier weights contained. Wood and wire hoops are also employed, and small economies may be effected by substituting wood or wire hoops for steel hoops.

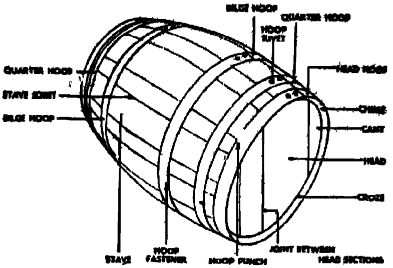

Fig. 32-9. Tight-barrel nomenclature.

As all slack barrels require the replacement of one head after being filled, it is important to note that bilge and quarter hoops should be driven tight after the head is in place and the hoops fastened by hoop-fastener nails or other means of equal efficiency. The head hoops and head are secured by nails or staples driven through the head hoop and into the head. The barrel supplier should be contacted for full details on the proper method of heading. When wood or metal cleats are used to reinforce the heads, they should be positioned perpendicular to the grain of the heads.

Tight barrels are those barrels having parts sufficiently tight to hold liquids without

Table 32-2. Slack-barrel Dimensions and Capacities (Approximate)

Capacity, gal	Head diam, in.	Stave length, in.	External bilge circumference, in.
12	12½	21	47 3
18	14⅛	24	54 1
21	15½	24	59 5
25	17⅛	24	65.4
30	16½	30	62.6
35	17⅛	30	68 0
38	17⅝	30	70 6
43	19⅛	30	74 8
46	20	30	77.0
48	19⅛	32½	74.9
51	19⅛	34	76 0
54	20	34	78 6
60	22	32	84 0
64	22	34	85 0

Table 32-3. Tight-barrel Dimensions and Capacities (Approximate)

Capacity, gal	Head diam, in.	Stave length, in.	External bilge diam, in.
5	10⅜	17½	38 5
10	12½	21⅜	47 5
15	14⅝	23⅜	55 0
20	16	23⅝	60.0
25	16½	29½	62 5
30	17¾	29½	67 5
50	21⅜	33¼	80.0
57	21⅝	35¼	83 0

They are manufactured in nominal capacities from 5 to 57 gal (see Table 32-3 for barrel dimensions and capacities). Tight barrels are of heavier construction than slack barrels and thus are higher priced. Because of this, tight barrels are frequently used as returnable containers.

Staves and heading of tight barrels are usually made of white oak, red oak, fir, gum, or ash. Various grades of white oak may be specified, *i.e.*, sap free, sap clear, tight sap, etc., depending on the quality of barrel required.

Staves and heading will range in thickness from ⅝ to 1 in. Staves are always butt-jointed, while the heading may be doweled and flagged or glued.

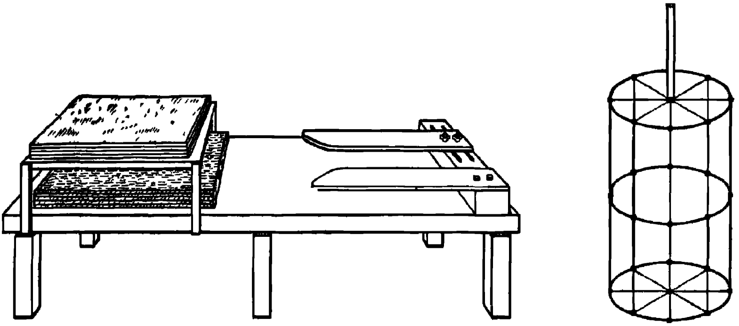
Hoops for tight barrels are always steel and may vary in number from six to eight hoops and in size from 1 in. wide by 19 gauge to 1¾ in. wide by 16 gauge. The locations of hoops are bilge, second quarter, first quarter oil head for eight-hoop barrels. When six hoops are specified, the barrels do not have the second-quarter hoops.

As tight barrels are used for liquids, they generally have an interior treatment of some kind, the most well known probably being the charred interior of whisky barrels. However, other linings such as animal glue, paraffin, asphalt, silicate of soda, and rubber lattices have been successfully employed.

Generally, tight barrels are filled through a bunghole located in the bung stave. Bungs should be treated with the same material as the drum interior, or a piece of suitably treated or coated cloth should be placed over the bunghole prior to driving the bung in place to assure maintaining product quality. Wood bungs should be driven with the grain of the bung parallel to the grain in the bung stave. Bungs should be secured by means of a bung strap placed across the bung and driven into the barrel.

LINERS

It is frequently necessary to utilize liners, which are not an integral part of a shipping container, with various types of containers in order to (1) prevent contents from sifting, (2) afford water and/or moisture-vapor protection, and (3) provide a chemically resistant material between contents and container. Liners may be fabricated from paper, flexible films, or combinations of both. They must be of a size to fit the interior dimensions of the shipping container without strain being placed on the liner or liner closure when contents shift during the course of handling and shipping. Liners must have sufficient flexibility and stretch to withstand the distortion which the shipping container may undergo. Liner closures may be made by tying, sewing, adhesives, or heat sealing. The type of closure will depend upon the type of shipping container, the liner material, and the degree of protection to be afforded by the liner.



Form for inserting liners in bags

Form for inserting liners in barrels or drums

FIG. 32-10. Devices for inserting liners in bags, barrels, and drums.

Paper liners, other than box or case liners, are usually creped or crinkled so as to stretch 15 to 25 per cent when tension is applied in the creped direction. Liners are creped or crinkled in one direction (single stretch) or in two directions (all-way stretch). Paper liners are made in various basis-weight papers and are designated by the basis weight of the paper before creping. They may be untreated paper, wax-impregnated (5 to 60 per cent by weight) paper, asphalt-laminated paper, or plastic-coated paper. Manufactured seams are usually made by sewing or with adhesives.

Film liners may be manufactured from polyethylene, polyvinylidene chloride, rubber hydrochloride, and other materials depending upon the chemical or moisture-vapor resistance required. These films do not require creping as they have inherent stretch characteristics to obviate the necessity for creping. Film liners are usually

1 to 5 mils in thickness depending upon weight of load and physical characteristics of the film. Manufactured seams are normally heat-sealed. Closure is made by tying or heat sealing. Increasing use is being made of film liners owing to their physical and chemical properties which permit the shipping of pastes and liquids in metal or fiber drums and corrosive solids in film-lined bags.

It is important that all liners be inserted in containers properly or their function may be lost. Devices similar to those shown in Fig. 32-10 are recommended for inserting liners in bags and barrels or drums. The correct procedure is to slip the liner over the form and, in the case of barrels or drums, to fold the liner "ears" over the bottom; insert the form in the container and fold the top of the liner over the top of the container; remove the form, fill the container, and then bring the top of the liner together and tie or wire the liner closed about 2 in. from the end of the liner. *Never tie the liner close to the product.* When film liners are used it is essential that the interior of the shipping container be free from sharp projections or burrs which might snag the liner. In addition, hermetically sealed film liners should have as much air as possible removed from the interior prior to sealing so as to avoid film breakage due to air pockets.

BOXES

Fiber Boxes. Two types of fiberboard are utilized for making fiber shipping boxes—corrugated fiberboard and solid fiberboard.

Corrugated fiberboard consists of two sheets called liners or facings between which is adhered a corrugated medium. Linerboard is normally made of pure kraft or jute (reclaimed papers) and is designated by caliper (points) and weight (pounds per 1,000 sq ft). Typical linerboard specifications are shown in Table 32-4.

Table 32-4. Typical Corrugating Medium and Linerboard Specifications

Type	Caliper, in.	Bursting strength, psi	Weight, lb per 1,000 sq ft
Corrugating medium:			
Straw	0.009	......	32–33
Kraft	0.009	....	26–28
Linerboard:			
Jute	0.012	....	50
	0.016	100–110	64
	0.023	140–150	85–90
	0.030	190–200	105–110
Cylinder kraft	0.016 dry	105–115	50–52
	0.016 semiwater	115–125	52–54
	0.016 water	125–150	54–56
	0.030 semiwater	185–200	90–95
	0.030 water	220–250	95–100
Fourdrinier	0.012	60–70	33
	0.014	75–85	38
	0.016 dry	85–100	42
	0.016 semiwater	100–105	47
	0.016 water	105–110	52
	0.023	135–150	69
	0.030 semiwater	145–160	88
	0.030 water	150–165	95

Note: To determine the weight of combined board, use the above figures plus factors of 1.55 and 1.33 for A and B flutes, respectively, for weight of corrugating medium, plus the following weights of adhesives:

	Silicate of soda	Starch
A flute	12 lb/1,000 sq ft	7–9 lb/1,000 sq ft
B flute	14 lb/1,000 sq ft	8–10 lb/1,000 sq ft

Linerboard is either of fourdrinier or cylinder construction indicating the method employed in the manufacture of the liners. Most kraft liners are fourdrinier type which results in a better balance of liner strength between "machine direction" and "across-machine direction" than is obtained with cylinder kraft or jute board. Also jute board usually weighs more per given area than kraft board of similar strength because of the extra material required owing to the use of reclaimed paper stock.

Corrugating material is usually strawboard, chestnut board, or kraft and is 0.009 in. thick and weighs 24 to 28 lb per 1,000 sq ft. Three types of corrugations are employed—(1) A-flute corrugations being 3⁄16 in. high and having 34 to 38 corrugations per linear foot; (2) B-flute corrugations, 1⁄8 in. high and having 50 to 52 corrugations per ft; and (3) C-flute corrugations, 3⁄16 in. high and 42 to 44 corrugations per ft. A-flute corrugations are employed for maximum cushioning, whereas B-flute corrugations are less easily crushed and are used for heavier loads. The C flute is essentially a compromise of the A and B flutes. When double-wall corrugated board is specified, it is usually composed of A- and B-flute corrugations, although some suppliers may be able to furnish AA, BB, or CC if necessary.

When corrugating material is combined with the liners, the grain of the liners is perpendicular to the corrugations. Hence the normal corrugated box is cut from the board so that the corrugations are vertical in the sides and ends of the box.

Solid fiber boxes are constructed of a solid board made up of three or more plies of paperboard glued together. Solid fiberboard may be constructed entirely of kraft or, as is usual, made with chipboard filler and kraft facings or linings. These facings may be treated with resins to provide high scuff resistance and resistance to water absorption. Increased resistance to water absorption is obtained if waterproof adhesives or barriers are employed in the fabrication of the board.

When specifying the strength of corrugated or solid fiberboard desired, it is customary to specify the minimum bursting strength per square inch (Mullen test) and/or the minimum caliper and weight of the liners or solid board.

Both corrugated and solid fiber boxes are made in a variety of styles and are sized to meet each product requirement. Styles of boxes in common usage are illustrated in Fig. 32-11. Close examination of the several styles illustrated will show

1. *Regular Slotted Box.* Manufacturers' joint or seam is at vertical edge. Inner and outer flaps are same width which, unless box is square, results in a gap between the inner flaps when box is sealed.
2. *Center Special Slotted Box.* Inner flaps are cut so that they will butt the same as outer flaps when box is sealed. This type of box has two thicknesses of material over entire top and bottom area. When box is longer than it is wide, the center special slotting requires the use of more material and an extra labor operation than regular slotted-style boxes of similar inside dimensions.
3. *Overlap Slotted-style Box.* Inner flaps are cut to same width as outer flaps, but the outer flaps will overlap at least 2½ in. or will overlap the entire width of box (full overlap).
4. *Telescope-style Box.* This box consists of two pieces—top and bottom. Each piece must be assembled by the user by wire stitching or staples. The top or cover telescopes the bottom resulting in two thicknesses of board along the sides and ends and single thickness of board of top and bottom. (Extra thickness results at ends or partway along sides depending on how the top and bottom are slotted.)

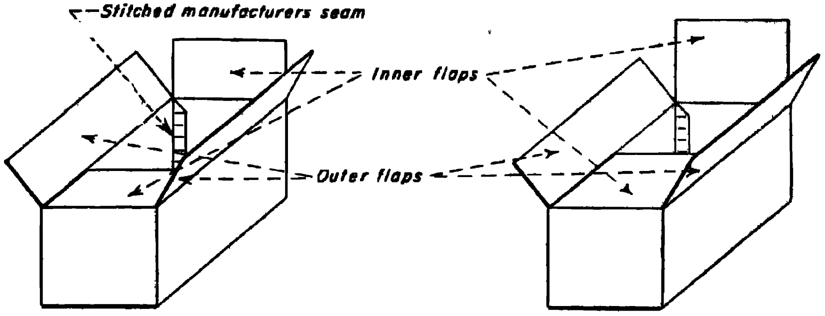
The size of a fiber box is always designated by the inside dimensions in the order of length, width, and height. It is well to remember that the flaps result in double or almost double coverage and that the area which the flaps will cover should be kept at a minimum to keep box cost down.

The slotted styles of boxes are made with a manufacturers' seam which is where the body of the box is joined. This seam may be made with a gummed tape, either cambric or reinforced paper, or by cutting the body of the box so that there is a flange which will fold against the side or end and be stapled to the side or end. The stapled manufacturers' joint is more rigid than the taped joint but also costs more owing to the extra board and a more laborious seaming operation.

Wood Boxes. Solid wood boxes are those constructed entirely of wood and utilizing nails for fasteners. The styles of wood boxes are shown in Fig. 32-12 and are as follows:

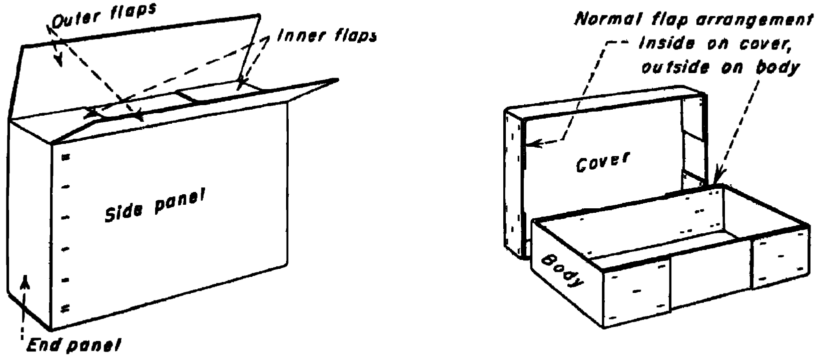
Style 1 is the cheapest and weakest construction of wood box. Top and bottom nailed into ends and sides, sides nailed into end grain of ends result in poor nail-holding power and frequent splitting of ends.

Styles 4 *and* 5 are a single-cleated-end box in which cleats may be placed on outside of box as shown or inside box (style 5). Cleats are of length equal to outside height of box minus ¼ in. Cleats are nailed to ends with nails clinched. Side-board nailing is staggered, nails being driven alternately into end grain of end boards and side grain of cleat. Cleats not only strengthen end by decreasing the unsupported length of the end board but also result in greatly increased nail-holding power of nails securing the sides. Style 5 boxes are used where box contents are of a shape which permits the placing of the cleats inside thereby decreasing the cubic displacement of the box. Style 2 boxes are sometimes made with the cleats horizontal and the grain of the end pieces running vertical. This is done to provide hand holds for lifting the box.



Regular slotted style

Center special slotted style



Full overlap style

Full telescope style

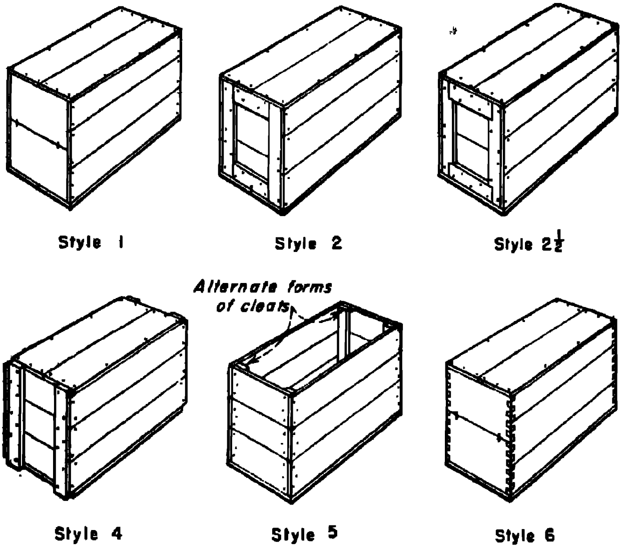
FIG. 32-11. Four styles of fiber boxes and the nomenclature of parts.

Styles 2 *and* 2½ are double-cleated-end boxes. Both vertical and horizontal cleats are provided on each end. These styles are used for heavy loads and for loads which will give a high end thrust (welding rods, bolts, etc.). For boxes having small end areas, it is frequently more economical to use double ends (two thicknesses of end boards) instead of cleating.

Style 6 is the lock-corner box. The sides and ends are joined by gluing the mortise and tenon joints. The top and bottom are secured by nails. This style box is normally classed as comparable to the load-carrying ability of style 1. However, through the use of good lumber and the proper cutting of the tenons and adequate gluing, this style is believed superior to style 1.

Assuming the choice of the proper style of box, the dependability of wood boxes is governed by (1) lumber used and (2) nailing. Wood should be good-grade box lumber free from loose knots, shakes, cross grain, and tight knots which will interfere with nailing. Lumber should not contain more than 18 per cent moisture. Wood is classified into four groups. The principal woods in each group are as follows:

Group I. White pine, ponderosa pine, spruce, cottonwood, yellow poplar, basswood, willow, cedar, white fir, butternut



Style 1 Style 2 Style 2½

Style 4 Style 5 Style 6

Fig. 32-12. Styles of nailed wood boxes.

Group II. Southern yellow pine, hemlock, Douglas fir

Group III. White elm, sweet gum, sycamore, black ash, black gum, tupel ft maple

Group IV. Hard maple, beech, oak, rock elm, birch, white ash, hickory

It will be noticed that these groups are arranged from soft to hard woods. The thicknesses of pieces and the size of nails used in box assembly depends upon what group of wood is used in the box construction. Table 32-5 shows the commonly accepted thicknesses to be used for the various groups of wood for boxes to carry loads up to 1,000 lb. Also shown in the table are the nail sizes for the thickness of parts specified.

In addition to the information above, the following should be borne in mind so that good box construction will result:

1. Keep inside dimensions to a minimum so as to reduce possible shifting of load.
2. Width of parts making up sides and ends should not be the same.
3. Nails should be cement-coated box, sinker, or cooler nails except those nails which are clinched. These need not be cement coated.
4. When unsupported span of box part exceeds thirty times the thickness of the part, additional cleats or battens of the same size as end cleats should be nailed across all parts to reduce the unsupported span length.

Table 32-5. Thickness of Wood-box Parts for Various Loads and Size of Nails to Be Used

	Group I and II woods			Group III and IV woods		
Gross weight, lb	Thickness of sides, top, and bottom, in.	Thickness of ends and thickness and width of cleats, in.	Nail size	Thickness of sides, top, and bottom, in.	Thickness of ends and thickness and width of cleats, in.	Nail size
100	3/8	1/2 ends with 1/2 × 1 5/8 cleats	5d	5/16	7/16 ends with 7/16 × 1 5/8 cleats	5d
250	9/16	11/16 ends with 11/16 × 2 1/16 cleats	6d	7/16	9/16 ends with 9/16 × 1 3/4 cleats	5d

1,000	....	......	3/4 × 0.023	....	....	9

Note: Boxes over 15 in. long should have two or more straps applied.

5. Large heavy boxes should have skids on bottom to facilitate handling.

6. Considerable increase in box strength may be obtained by correct application of steel strapping. Steel strap reinforces the nailing and should be positioned with that thought in mind. Table 32-6 shows the commonly used sizes of flat and wire strap and the number of straps to be used for various box weights.

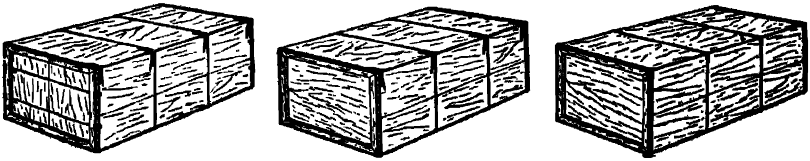

Fig. 32-13. (*Left*) All-Bound box. (*Center*) Rock-Fastener box. (*Right*) Regular-Twist box.

Wire-bound boxes are constructed of veneer, plywood, or resawn lumber having cleated ends and with girthwise wires stapled to the box blank for reinforcement. The use of wires permits decreased lumber thickness resulting in low tare weight and low initial cost. Three styles of wire-bound boxes are in common usage: (1) All-Bound, (2) Rock Fastener, and (3) Regular Twist (see Fig. 32-13).

The *All-Bound box* has the ends attached to the body by means of wires. The box is shipped knocked down and is set up by passing the ends of the wires attached to the box ends through the solts in the cleats and bending the wires back. No nails are required for assembly or closing this style of box.

The *Rock-Fastener box* consists of a body blank and two ends, the ends being separate. The parts are shipped knocked down, and the box is assembled by nailing through the body cleats into the end cleats. Closure is made by use of the rock fasteners.

The *Regular-Twist box* is essentially the same as the rock fastener with the exception that the closure is made by twisting the wires together which extend beyond the closing edge of the box.

Each of these styles of wire-bound boxes can be obtained in thickness from 1/10 to 3/8 in. for veneer and plywood and 3/16 to 3/8 in. for resawn lumber.

The cleats furnished on wire-bound boxes may be either mitered or tongued and grooved. The former is considered more desirable from a strength standpoint.

Binding wires are available in a number of gauges and hardnesses and may be galvanized or black. It will be seen that the rock-fastener type of closure is designed for multiple openings, and accordingly the wire used must not be too hard or soft. The regular-twist closure is destroyed when opened, and soft wire is desirable for effecting a good twisted closure. Of interest is the fact that, if a rock-fastener closure breaks, a new closure piece may be spliced onto the box and satisfactory service continued.

Wire-bound boxes are manufactured in many different shapes besides the conventional rectangular container, depending upon the shape of the contents. In addition, wire-bound crates are also marketed.

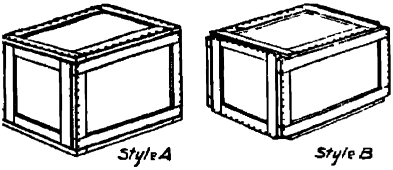

FIG. 32-14. Two styles of cleated plywood or fiberboard boxes with cleats at each edge of each panel.

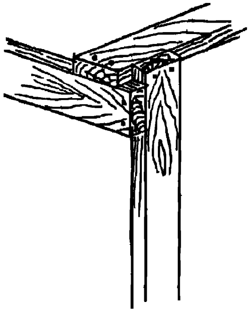

FIG. 32-15. Three-way cover construction for crates.

Inasmuch as wire-bound boxes are manufactured on automatic equipment which requires considerable setup time, it is not economical to consider using wire-bound boxes unless several hundred or more of one size of box can be purchased at one time.

Cleated Plywood and Fiberboard Boxes. Cleated plywood (fiberboard) boxes consist of panels of plywood having cleats attached along the edges. These panels are assembled by nailing. There are many styles of cleated boxes depending upon the number and position of the cleats. The strongest constructions are those which have two cleats at each box edge permitting side-grain nailing throughout. These styles are known as style A and style B and are shown in Fig. 32-14.

Cleated boxes are used for carrying weights up to 1,000 lb. The strength of the box depends upon the thickness of the plywood and the size and number of cleats and battens. The battens are used to reduce the unsupported span of the plywood and add considerable strength. The plywood is stapled to the cleats by wire staples or by flathead nails. Both staples and nails should penetrate the cleats and be clinched.

The same type of box utilizing fiberboard, either corrugated or solid fiber, is in use. The same method of construction is employed, although in attaching the cleats to the fiberboard, glue is sometimes employed. Boxes with fiberboard panels are not used to carry such heavy loads as plywood paneled boxes.

Crates. It is impossible in the space reserved to establish any concrete facts concerning proper crate construction. In a very general manner the following is offered as a guide:

1. Determine if open or closed (sheathed crates may be employed).
2. If size and weight of object to be crated are not excessive and quantities are of a good magnitude (1,000 and over), consider the use of wire-bound crates.

3. Mount the object on skids whenever possible.
4. Employ three-way corner construction which gives best nailing at corners (see Fig. 32-15).
5. Use diagonal members to prevent distortion of crate by weaving. The angles which the diagonal member makes with the horizontal should not be less than 30 or greater than 60 deg.
6. Use good-sized lumber for frame members, and cut down unsupported spans by intermediate vertical and horizontal members.

GLASS DEMIJOHNS AND CARBOY BOTTLES

A large number of 5-, 6½-, and 13-gal-capacity carboy bottles are used by the chemical industry as returnable containers, generally carrying acids. The 5- and 6½-gal bottles are machine made. The former are obtainable with either a cork or screw finish, whereas the latter are obtainable with screw finish only. Figure 32-16 shows data pertaining to the 6½-gal bottle.

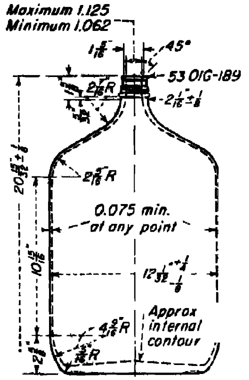

FIG. 32-16. A 6½-gal carboy bottle.

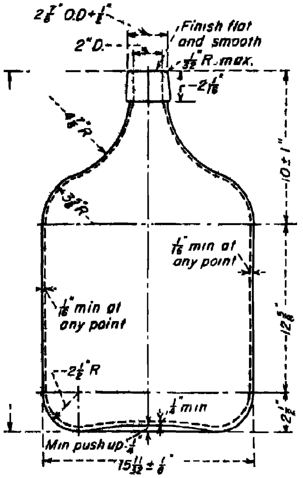

FIG. 32-17. A 13-gal carboy bottle.

The 13-gal carboy bottles are manually blown and may be obtained with either a plain cork finish or a ground-glass finish for a corresponding ground-glass stopper. Figure 32-17 shows the standard 13-gal bottle.

Carboy bottles must be packed in a shipping container for transportation. If dangerous articles are to be shipped, there are stringent requirements on the construction of the boxes and cushioning which must be used (see Agent H. A. Campbell's Freight Tariff No. 4). For nondangerous commodities the shipping container may be a fiber carton or drum, plywood drum, slack barrel, etc., with sufficient interior cushioning to prevent bottle breakage. Normally, it has been found to be economical to pack bottles in a substantial wood box with interior cushioning of relatively long life and use the carboys as returnable containers.

PACKAGING EQUIPMENT

It is again emphasized that this section deals with the "industrial" type of containers previously described. Other than equipment for container assembly, the users of "industrial" or bulk containers are essentially interested in equipment for weighing, filling, and closing. These operations will be discussed in the following material.

General. The proper choice of weighing and filling equipment will vary with the characteristics of the products to be handled, the filling rate required, and the capital expenditure which may be allocated. In many instances, there are several choices of equipment for a specific job. It is the engineers' duty to study the equipment available and utilize that which will return the greatest savings commensurate with investment. It is hoped that the following review will aid engineers in their job.

It is essential for accurate weighing of materials, dry or liquid, that uniform flow of the materials to a scale or to filling equipment be maintained. Primarily, in the case of dry materials, this will depend upon proper bin design. For free-flowing granular or crystalline products, this is not difficult, and conical bins may be used without fear of difficulty. However, with fine powders which will deaerate in storage and pack or "bridge" in a bin, designing to prevent this is difficult. With such products, it is suggested that the following be considered:

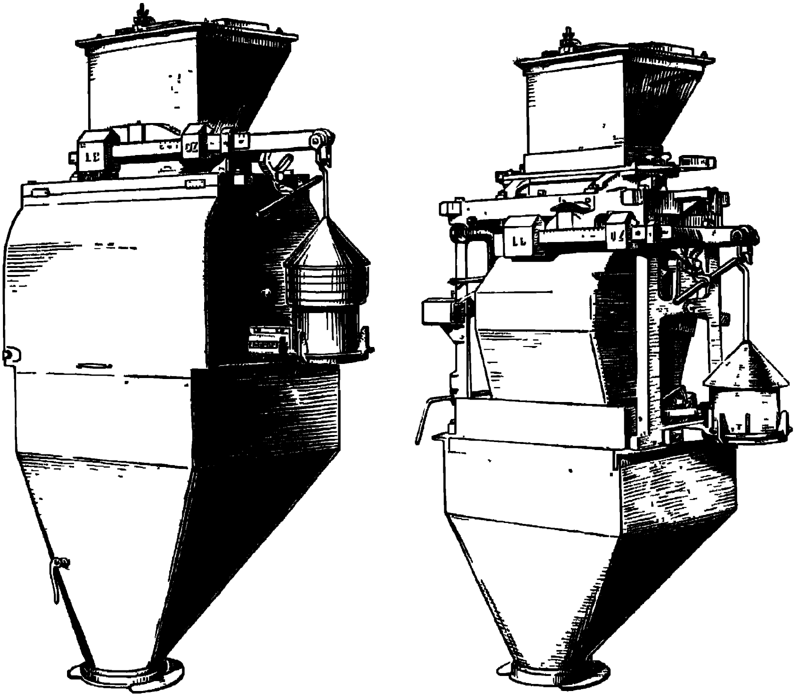

Fig. 32-18. Net-weigh scales. (*Left*) Hoepner Model 02 fully enclosed automatic discharge with counter. (*Right*) Hoepner 02.

1. Design bin with two vertical adjacent sides and two sides at an angle well in excess of the angle of repose of the material going in the bins.

2. Keep material moving by utilizing either internal or external vertical conveyor which will constantly remove material from the bottom of the bin and deposit it at the top.

3. Insulate bins from normal building vibration in order to keep packing tendency to a minimum.

If uniform flow of material is maintained, weighing equipment will give excellent results. With some types of filling equipment, it is necessary not only to obtain a uniform flow but also to maintain a uniform amount of material in the hopper of the filling equipment. This is easily accomplished by (1) having a hopper whose minimum size is at least twice the capacity of the container to be filled and (2) installing bin-level controls at a minimum and maximum hopper capacity which experience has indicated will give the best results.

Another factor which must be kept in mind when filling containers with dry materials is that, with all containers other than bags, it is desirable to fill them to their maximum capacity. With products that deaerate or settle, this means that filling equipment or auxiliary equipment such as vibrators which will settle the material as it is being packaged should be employed. However, a dense tight-filled bag is not so safe a carrier as one which has some slack. Accordingly, care should be exercised on the amount of deaerating obtained with bag-filling equipment.

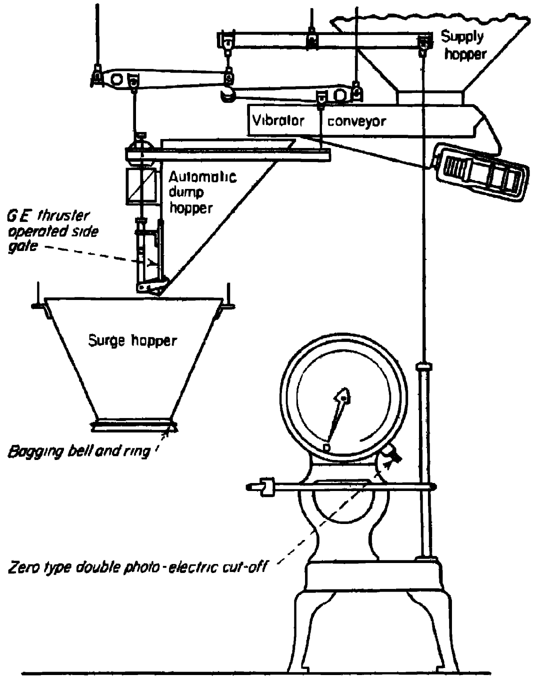

FIG. 32-19. Toledo automatic weighing and discharging equipment for filling bags. One or two vibrating conveyors may be used to feed material to the weigh hopper. These feeders may operate at one or two speeds depending upon filling rate and accuracy required.

Weighing Equipment. Two general methods of weighing are employed: (1) net weigher and (2) gross weigher.

In net weighing, the amount of material to be placed in a container is weighed independently of the container and then discharged into filling equipment or direct to a package. This type of weighing is considered more accurate than gross weighing, as variations in the tare weights of containers are not factors, and the total weight on which the percentage accuracy of the scale operates is less than with a gross weigher (see Fig. 32-18). Illustrated are several types of net-weigh scales. Bucket- or hopper-type scales, whether they be of the beam or dial indicator, are uniformly net-weigh scales in which material flows through a gate into the top of the scale bucket. As the weight of the material approaches the desired net weight, the movement of the weigh hopper causes the inlet gate to close, partially thus slowing the amount of incoming material to a dribble. When the final weight is reached, the gate is completely shut by mechanical trip. The charge is then released from the weigh hopper by push button or other manual control. Completely automatic weighing is accomplished by the same principle but utilizing mercoid switches and solenoids, etc., to release the charge and start another weigh cycle. Weighings at the rate of five to ten 100-lb units per min may be obtained.

Similar automatic weighing may be achieved with a dial scale equipped with magnetic or photoelectric cutoffs. With this setup weigh hopper and feed mechanism are actuated by the dial indicator making a magnetic circuit or intercepting a light beam at a predetermined setting. When the final weight is in the weigh hopper, a thruster is actuated which releases the charge from the hopper (see Fig. 32-19).

Other methods for obtaining accurate final weights by controlling the feed to the weigh hopper are (1) belt feed, (2) screw conveyors, and (3) vibrating feeders. Very close tolerances are realized by employing a bulk and a dribble feed simultaneously, with the bulk feed being stopped a few pounds short of required weight. The choice of method used will depend upon the physical characteristics of the material being weighed, weight accuracy desired, and production rate. It should be borne in mind that every product costs money to manufacture and that over-all plant yield is determined by the pounds of material sold. The closest tolerance consistent with product and packaging labor costs should be the goal of every weighing operation.

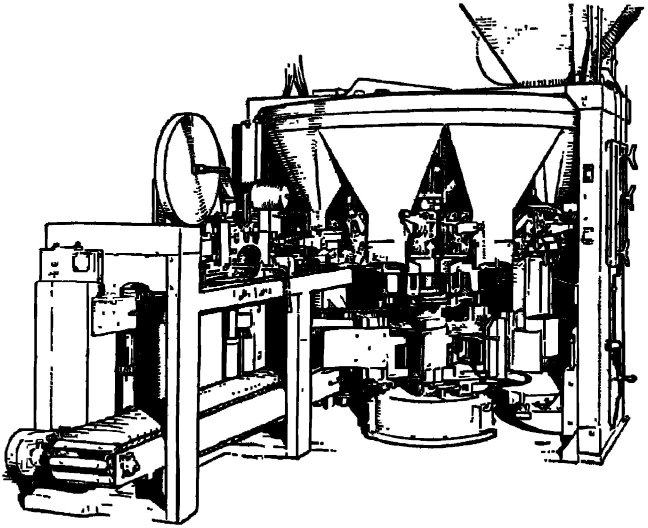

FIG. 32-20. Model A Bagpak. High-speed automatic weighing, filling, and sewing of multiwall paper bags.

Platform dial and beam scales are commonly used for gross weighing. The container is placed on the platform and tare weight adjustment made or the tare weight noted and added to the desired net weight. Dial scales for manual gross weighing are frequently used, as the approach of the indicator to the final weight acts as a signal to the operator to throttle the discharge valve and reduce the flow of material until the final weight is reached.

Bagging Equipment. *Open-mouth Bags.* The scales heretofore described and equipped or supplemented with bag holders may be used for accurate filling of open-mouth multiwall paper and texile bags at rates up to six 100-lb bags per min. For high bagging rates of fifteen to twenty 100-lb bags per min, the Model A Bagpak machine shown by Fig. 32-20 may be used. This unit weighs, fills, and closes bags at the described rate using but one operator. The unit consists of a battery of three or four scales mounted over a rotary turntable on which are suspended a number of bag holders with surge hoppers. The operator positions bags on the holders as they rotate. When the empty bags are indexed to the proper position under the scales, the charge is released into the bag. As the filled bags continue around the turntable on a joggling roller conveyor, the material is settled leaving sufficient outage for the bags to be sewn. When the bags reach a position approximately 270 deg from the operator, they are automatically transferred to a conveyor running tangential to the turntable and with the help of chain belts the bags are guided through a sewing machine and then to conveyor to warehouse or freight car. A similar smaller unit for ten to twelve bags per minute is also manufactured.

A simple and relatively inexpensive bag holder and scale for manual filling and weighing is shown in Fig. 32-21. This unit is a bag holder mounted on a small hopper

pivoted on a frame. The frame may be stationary or pivoted. The bag holder and hopper are at one end of a lever arm to which weights equaling the gross weight are attached at the other end. An "under-over" dial indicator guides the operator in adjusting the flow of material to the bag. This scale permits filling to final weight in one operation, the weight accuracy depending upon the skill of the operator.

Many dry materials are of a nature which prohibits their being discharged from a scale hopper into a bag because of serious dusting. In such instances where open-mouth bags are used, it is desirable to fill the bags by means of an auger packer (see Fig. 32-22). This equipment consists of a small hopper feeding a vertically mounted auger. A counterweighted platform serves as a base for the container during the fill time. The auger may be belt- or direct-motor-driven through a clutch. In addition to the counterweight on the platform, the packers may be obtained with an adjustable brake shoe which gives added compression against which the filling auger must act. In operation, an empty bag is slipped over the end of the tube surrounding the auger and up the tube until the bottom of the bag is at or near the bottom of the tube. A foot pedal or push button is then actuated which causes the platform to rise until it is directly under the bag. At this location the platform trips a switch which throws in the clutch and starts the auger. As material is forced into the bag, the bag and platform descend until a second switch is contacted which disengages the clutch, thereby stopping the flow of material. The platform continues to descend until it is at floor level where the bag is removed. Inasmuch as this is a volumetric filling method, it is necessary to checkweigh the filled bag prior to closing. While considerable deaeration of product may be realized by adjusting the brake pressure and using augers of varying pitch, it is frequently necessary to compromise the deaeration with dustless operation and higher filling rate in order to achieve the optimum operating efficiency.

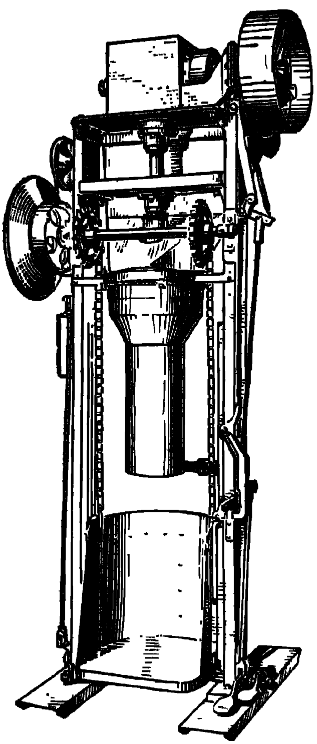

FIG. 32-22. Vertical auger packer for filling bags, barrels, and drums.

Valve Bags. Numerous types of valve-bag filling equipment are available depending on the bagging rate desired and the physical characteristics of the material to be bagged. Basic types of valve-bag packers are (1) impeller, (2) belt, (3) auger, and (4) gravity. The principles of each type are explained below.

1. IMPELLER. The impeller-type packer consists of a housed rotating shaft on which are mounted blades (similar to a turbine). Material is fed from a hopper into the housing where it is picked up by the blades and given sufficient velocity to force it through the spout outlet of the housing on which the bag is held. The impellers may be mounted vertically or horizontally depending upon material feed. This type of packer is normally used with nonabrasive materials which will not break down by impact of the impellers.

2. BELT. Belt packers (see Fig. 32-23) are used for fast bagging of free-flowing granular and crystalline products. The belt packers may be either the preweigh or gross-weigh type. If preweigh, the material is discharged from a scale into the hopper of the packer. The hopper outlet is constricted so that the material is fed into a groove in a rotating wheel. The material is held in the groove through 90 deg change in direction by an endless belt which runs against the flanges on either side of the wheel. As the material leaves the groove, it is forced through the filling spout. The preweigh type of packer permits vibration of the bag during the filling cycle. This is accomplished by automatic joggling of the rest on which the bottom of the bag is placed.

The gross-weigh belt packer operates on the same principle as the preweigh except that there is a shutoff valve at the inlet to the rotating wheel, and the filling spout and bag rest are part of a beam scale. In operation, a control lever is positioned which causes the inlet valve to open and the grooved wheel to rotate. When the predetermined weight of material is in the bag, the lever arm trips which closes the inlet valve and disengages the clutch. It will be seen that uniform feed of material to the rotating wheel is essential if accurate weights are to be obtained. At the instant of cutoff the amount of material between the cutoff valve and the outlet of the filling spout will be added to what is already in the bag. If this amount is not fairly constant for each bag, poor weights will result.

3. AUGER. Auger-valve bag packers (see Fig. 32-24) are designed to be used on materials which are light and tend to deaerate and pack. Material is fed to the packer

hopper which is equipped with a ribbon agitator to prevent bridging. The material drops into an auger running from 1,200 to 2,000 rpm. This auger forces the material out the filling spout on which the bag is suspended. Frequently this type of packer is used for products which cannot be preweighed and discharged. In such instances, two types of auger packers are available. One type depends on a timer which stops the auger after a predetermined period of time. Here again it is of utmost importance that uniform feed to the packer be maintained for accurate weights. The second type recently introduced commercially weighs the material as it is forced into the bag and trips a switch stopping the auger when final weight is reached.

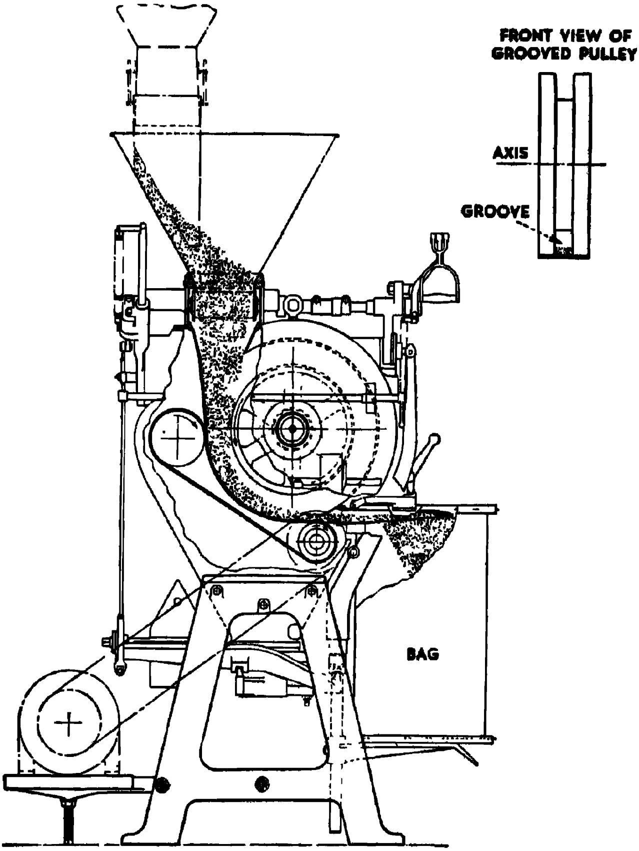

FIG. 32-23. Gross-weigh belt-type valve bag packer.

4. GRAVITY. Gravity-valve bag packers (see Fig. 32-25) are employed for free-flowing crystalline or granular materials where relatively low bagging rates are desired. The unit consists of a small hopper tapering to a filling spout. It depends on the free-flowing characteristics of the material and gravity to fill the bag. Material may be either preweighed and discharged into the hopper of the packer, or the packer may be mounted on a platform scale and the operator control the flow of material to the packer as indicated by the scale.

In considering valve bags and valve-bag packers, it should be kept in mind that they are designed primarily for high bagging rates with small labor requirements. This usually prohibits checkweighing and adjusting of every bag. However, because of the simplicity of closure inherent in valve bags, their use in broader applications is becoming more widespread. Weight adjustment may be made by means of scoops which will easily fit in the valve opening of the bag. Several scoops holding different quantities of the same material will facilitate the adjusting of bag weights.

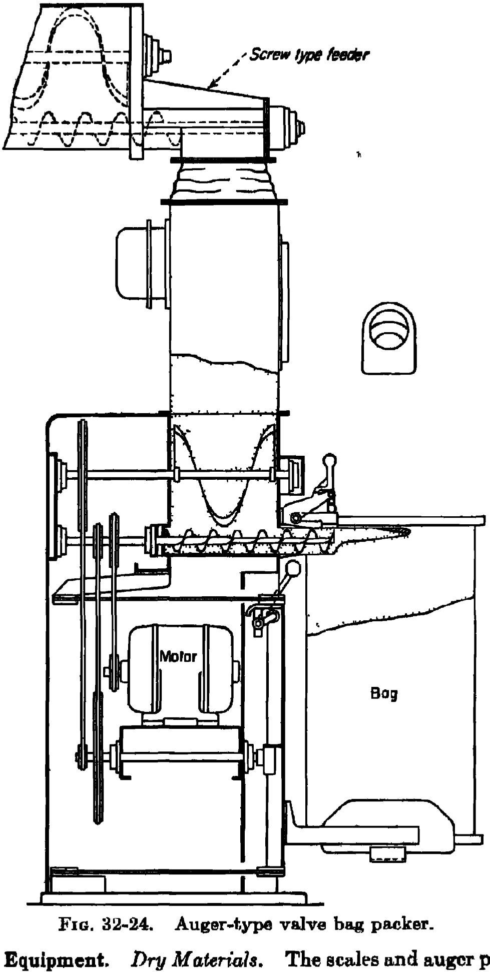

FIG. 32-24. Auger-type valve bag packer.

Drum-filling Equipment. *Dry Materials.* The scales and auger packers described in the foregoing section may also be used for filling drums and barrels. As previously stated, with these containers it is desirable to have them filled to capacity during storage and transportation. This not only reduces container, handling, and freight costs per unit of net weight but also permits better and safer storage and handling. To increase the amount of material which can be packed in a container, consideration should be given to (1) mechanical and electrical vibrators, (2) hydraulic jolters, and (3) vacuum deaeration. Mechanical vibrators are available having a fixed amplitude and frequency of vibration. Electrical vibrators have a fixed frequency, but the amplitude may be varied by means of a rheostat. Generally, the mechanical and electrical vibrators have a relatively high frequency which with some very light finely ground powders will not result in deaeration. Such materials may deaerate if the frequency of vibration is sharply reduced and the amplitude increased. Such an action may be obtained with an hydraulic jolter. The third method of deaeration—vacuum bell—is accomplished by placing the filled container in a vacuum chamber and after the proper amount of vacuum is reached opening the chamber to atmospheric pressure.

In effecting deaeration by the mechanical, electrical, or hydraulic equipment, two methods are optional: (1) vibrate the container while filling, or (2) fill the container, vibrate, and then refill the volume gained by vibration. If preweigh scales are used, it is possible to vibrate while filling. However, if the container rests on a scale platform while being filled, it is impossible to vibrate until after filling. In order to do this and avoid further filling, the use of a collar which will fit on top of the drum and increase the drum capacity temporarily may be used. After the material has settled to where it is all within the confines of the drum, the collar can be removed and the drums closed.

Equipment for filling rigid containers with powders by vacuum has been recently marketed. While similar equipment has been in use for 8 to 10 years for filling small containers, its adaptation to bulk containers is relatively new. Vacuum filling of powders is a quick dustless operation with a packed density of product higher than may be achieved by any other known packaging method. A vacuum filler consists of a vacuum source, vacuum tank, filter, valve assembly, filling head, and hopper and elevating container platform. The filling head is illustrated in Fig. 32-26. It will be noted that the filling head consists of centrally located holes connecting the bottom of the hopper with the container and two separate vacuum inlets which are screened. In operation a container is placed on the platform which ascends and seals the top of the container against a gasket in the filling head. Vacuum is then admitted in one side of the head which evacuates the air from the container. The pressure differential between the evacuated container and the material in the hopper causes the latter to rush into the container. After a fixed time interval, the vacuum is released on the one side of the head and applied at the other. When the vacuum is released, that side is open to atmospheric pressure, and the incoming air cleans the material off the screen on that side of the head. The timing of the application of vacuum to each side of the head and the number of cycles to a filling operation are controlled by a valve mechanism.

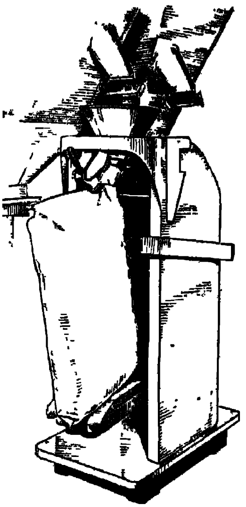

Fig. 32-25. Gravity-type valve bag packer.

Liquid Materials. Liquids may be packaged in drums or other containers by volume or weight. A simple inexpensive volume filler utilizes a float valve to cut off the flow of liquid when the proper level is reached in a container. The depth to which the valve will go in a container is adjustable. With volumetric filling of this type it is important that containers be uniform size.

Another more accurate method of volume filling is done by a metering device. Such a meter measures the amount of liquid flowing through it and automatically cuts off a set volume. The meter is equipped with temperature controls to compensate for temperature variations of the liquid which in turn affect volume. For best results a constant pressure head should be maintained. These meters may be equipped with a control valve for reducing pressures to practical working pressures and with strainers for ensuring a product free of foreign material. The meters are available in stationary and portable models.

Several semiautomatic and automatic methods of filling liquids by weight are utilized. Illustrated in Fig. 32-27 is the Vol-U-Meter method consisting of a valve and a mercoid switch with a trip lever. The latter is attached to the frame of a beam scale in such a manner that when the beam falls, indicating the desired weight is in the container, the beam hits the trip lever which actuates the mercury switch and closes the valve. The valve is opened by moving the manually operated lever.

A second method of weighing liquids is accomplished by utilizing a dial scale equipped with magnetic or photoelectric cell cutoffs connected to a two-stage solenoid-operated valve. In operation, the container is placed on the scale platform and the tare weight adjustment made. The desired net weight is fixed on the beam balance. As the dial indicator approaches the zero mark on the dial, it intercepts a light beam, and the first stage of the solenoid valve is actuated causing the valve partially to close. As the indicator continues to zero, the light beam is again free, and the second stage of the solenoid valve is actuated which shuts the valve completely. The extent to which the second stage of the valve permits the valve to stay open is adjustable so that whatever "dribble" flow is required can be obtained.

FIG. 32-26. Section of vacuum-filling head for filling rigid containers with powdered material. Flexible containers may also be filled by this principle by placing a rigid shroud around the container and evacuating the air between the shroud and container at the same time that air is evacuated from the interior of the container.

Case Packers. Case packers are utilized for semiautomatically loading canned goods and bottled goods in fiber and wood boxes and small paper bags in paper shipping containers.

Round cans are usually cased in equipment similar to that shown in Fig. 32-28. The cans enter on their sides and are guided into a form holding the desired number.

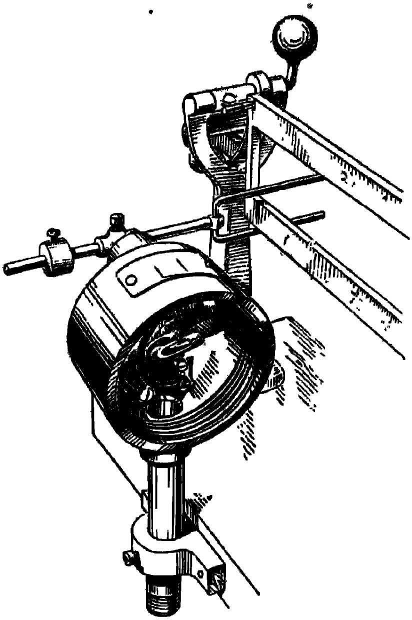

FIG. 32-27. Control switch which is attached to beam scale for actuating Vol-U-Meter filling valve.

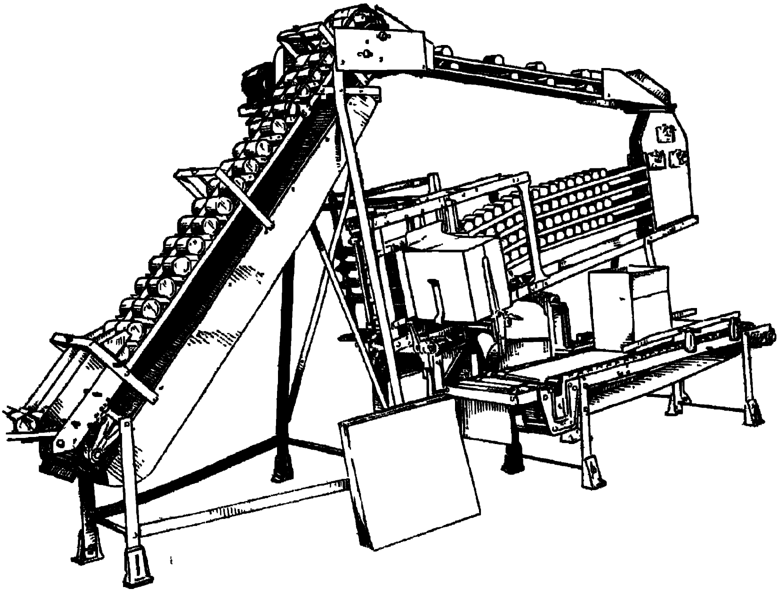

FIG. 32-28. Can case packer.

As one layer fills, the form drops, permitting the next layer to go into position. When the form is filled, an empty carton is placed over the opening and a foot pedal depressed. This actuates a thruster which pushes the cans into the carton. The carton is then lowered to a conveyor leading to a carton-sealing machine.

Bottled goods are kept vertical and separated on a conveyor into the number of rows which is equivalent to the rows of bottles in the case—usually four. The four rows then move forward simultaneously into a jig under which an empty carton is placed. A lever is tripped which lowers the bottles into the case (see Fig. 32-29).

Container Bag Packer. A paper shipping container bag is a multiwall paper bag in which a number of small bags or "pockets" are shipped. Equipment for filling container bags operates on somewhat the same principle as the can packer. Bags to be packed come to the packing station in a single line. The number of bags to go across the width of the container bag are then pushed by a thruster into a form over which the container bag has been placed. One layer of bags is positioned at each stroke of the thruster.

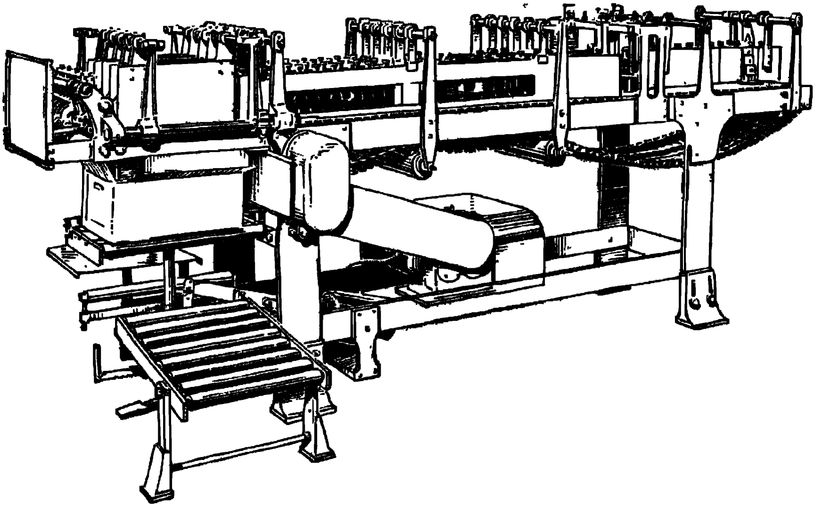

FIG. 32-29. Bottle case packer.

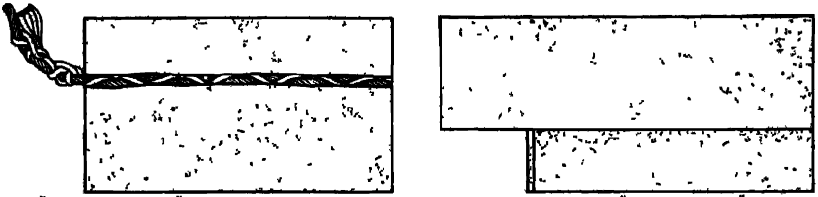
Closing and Sealing Equipment. *Open-mouth Bags.* Multiwall open-mouth paper and textile bags are closed by wire tying, stapling, and sewing. The first two methods are usually employed where bag production is low. This is for the reason that these methods require longer bags than the sewn closure, and thus bag cost is higher. When bags are wire tied, the mouth of the bag is gathered and a wire tie bent around the gather and twisted together by means of a tool. The gathering and application of the wire tie may also be performed automatically on equipment manufactured by the Hamer Machine Company of Minneapolis, Minn. If bags are paper and made of four or more plies, it is difficult manually to gather so much paper in which case the inner ply or plies may be folded down on the product and the outer three plies used for making the closure. When wire ties are used, care should be exercised that the tie is not applied close to the product. There should be 8 to 12 in. of outage, depending upon the bag size, and the tie applied 1 to 2 in. from the end of the bag.

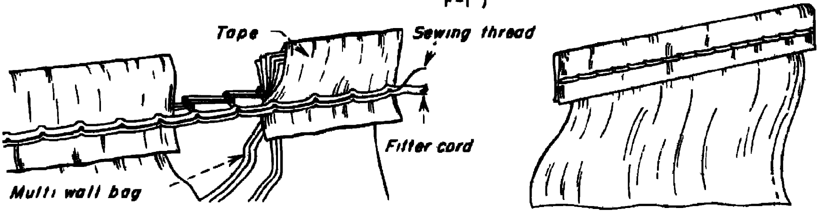
Stapled closures are made by folding down the top of the bag 1 to 2 in. and stapling through the fold. A second fold will make the bag more siftproof. Standard wire-stapling machines are used for this operation. If the bag is placed on a roller conveyor and the stapling head placed at an angle rather than horizontal, an easier operation will result.

The majority of open-mouth bags are closed by sewing Sewing machines utilizing a chain stitch, double-locked stitch, and patented "cushion" stitch are available. The details of these stitches are shown in Fig. 32-30. The two latter types of stitch are those normally used in closing paper bags, while the first two types are used for closing textile bags.



The "Cushion Stitch" closure before taping This type closure effected by models "E-I" and "F-I" Bagpackers

The taped and sealed "Cushion Stitch" closure This type closure effected by models "A" and "D-A" (Tape not applied by models "E-I" and "F-I")



Tape-bound sewed closure for multiwall paper bags

Fig 32-30 Sewn closures for multiwall paper bags

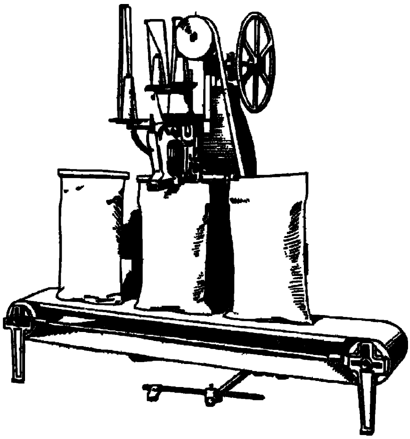


Fig 32-31. Union Special Style 21800 bag sewing machine with Style 80600H sewing head and 21844 tape-sealing attachment.

The Union Special Machine Company bag-sewing machines are available in several styles. A commonly used one is shown in Fig 32-31. Various types of sewing heads are applicable to the different machines. Sewing head styles 80600AC and 80600AD are used for closing heavy-weight textile bags. The AC produces the double-locked stitch and the AD the chain stitch. Styles 80600E and 80600F may be used for both paper and textile bags. A filter cord is normally used with paper bags. This filter cord fills the needle holes and prevents sifting. Sewing head style 80600H makes a tape-bound sewn closure with the stitches penetrating the crepe-paper tape. Simultaneously, a filter cord is run. This head produces the double-locked stitch and has an automatic mechanical tape and thread cutter.

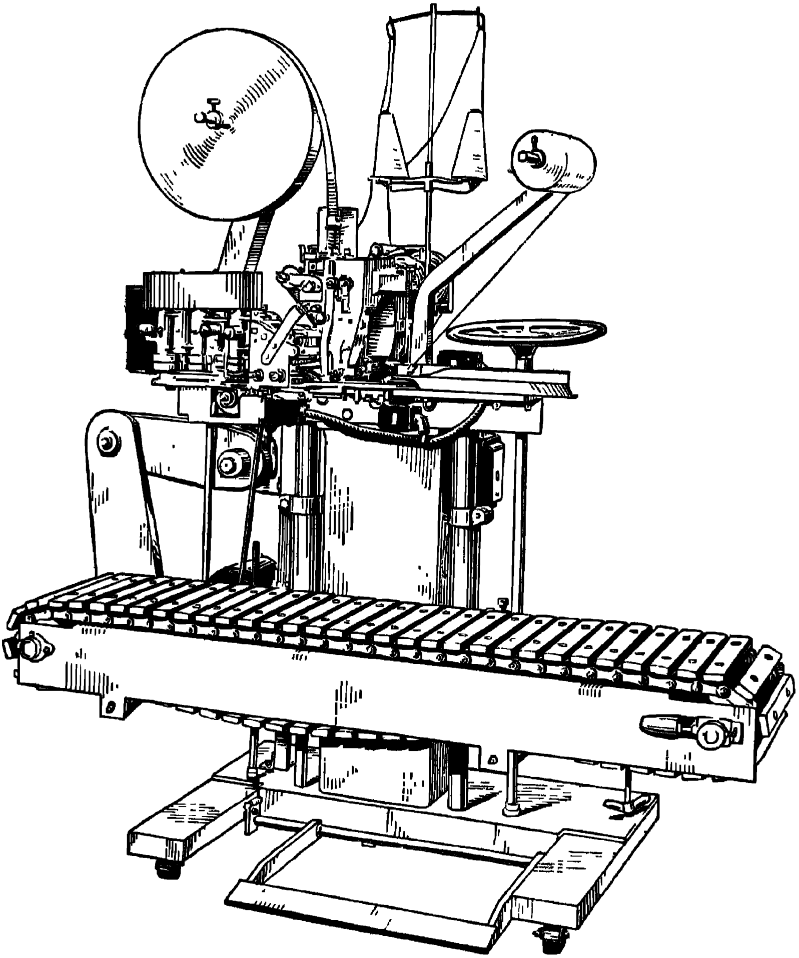

FIG. 32-32. Model DA Bagpak sewing machine for applying tape over "cushion-stitch" closure.

The Bagpak sewing machines are also available in different styles and with heads producing different types of stitching. In wide use is the Model DA Bagpak for closing multiwall paper bags (Fig. 32-32). This unit produces the "cushion stitch" illustrated. Paper tape is applied *over* the stitching if desired.

Fiberboard boxes may be closed by application of gummed paper or cambric tape to all open seams, by application of adhesive to the flap area, or by stapling Adhesive sealing may be entirely manual, semiautomatic, or completely automatic. A carton sealer of the latter type is shown in Fig. 32-33. Cartons are fed automatically to the entrance of the gluing unit where the outside top and bottom flaps are turned outward and pass under glue rolls. The flaps are then turned to their normal closed position, and the carton enters the compression unit consisting of spring-mounted idler rolls pressing down on the top flaps. The carton is carried through the gluer by a push-box conveyor and through the compression unit by a belt conveyor running on a steel bedplate. Speeds as high as 40 cartons per min may be obtained depending on the speed and box spacing of the push-box conveyor and the length of the compression unit.

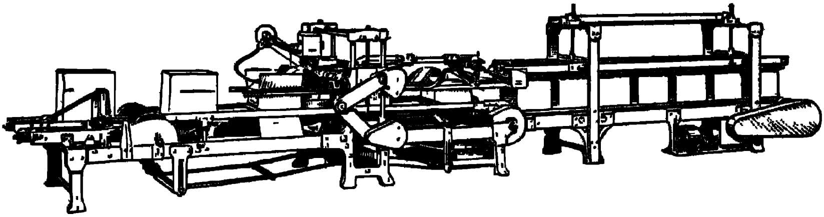

FIG. 32-33. Automatic case sealer (gluer and compression unit).

Overlapping cartons may be sealed by adhesive or by wire-stapling machines in which the anvil is thrust under the two overlapping flaps and the top stapled. Regular slotted boxes may be stapled closed by a machine utilizing a preformed staple. Two anvils having knife edges penetrate the fiberboard. The preformed staples are clinched against the anvil heads, and the anvils retract.

Federal Specifications for Containers

LLL-B-631	Boxes, fiber corrugated
LLL-B-636	Boxes, fiber, solid
NM-B 601	Boxes, wood-cleated plywood
NM-B-621	Boxes wood nailed and lock corner
NM-B-631	Boxes, wood, wirebound
RR-B-116	Barrels steel Type 5
RR-C-96	Cans steel (tinned-plate, terne-plate, and black sheet), friction covers
RR-D 701	Drums, metal Types 5A, 5C, and 5D (for acids and other dangerous articles)
RR-D-726	Drums, steel, Type 5 (for inflammable or poisonous liquids)
RR-D-729	Drums steel, Type 5B (for liquid petroleum products)
RR-D-741	Drums steel, Type 6C (for inflammable solids and oxidizing materials)
UU-S-48	Sacks, paper, shipping

INDUSTRIAL GLASS[*]

BY HAROLD G. VOGT

Physicist, Corning Glass Works

DEFINITION AND TYPES OF GLASSES

Glass is an inorganic product of fusion which has been cooled to a rigid condition without crystallizing.[†] It is typically hard and breaks with a conchoidal fracture. Although basically homogeneous and transparent, masses or bodies of glass may be made colored, transluscent, or opaque by the inclusion of dissolved, amorphous, or crystalline materials.

Glass is made by heating a mixture of dry, powdered or granular materials at about 2800°F in a refractory container until a viscous, homogeneous liquid is formed. The proportions of the raw materials in the batch are seldom in the ratios corresponding to those of chemical compounds. Rather the proportions may be varied continuously over relatively wide ranges to give glasses with some physical and chemical properties varying continuously over wide ranges, while some properties remain practically constant, and others vary over small ranges. Moreover, there is considerable choice as to which and how many ingredients are to be used. Through a study of the properties of some 50,000 glasses, it has been possible to select formulas that are best fitted for specific applications. About 400 different glasses are melted commercially each year. They differ considerably in some of their properties. Of these glasses a relatively small number have such good all-around usefulness that they are melted continuously and in great volume.

The great bulk of commercial production is commonly classified in the following chemical types of silicate glass. Listed in order of decreasing costs, decreasing softening temperatures, decreasing thermal-shock resistances, and of increasing thermal-expansion coefficients they are (1) 99.8 per cent silica glass, *i.e.*, fused quartz or fused silica; (2) 96 per cent silica glass; (3) borosilicate glass; (4) lead glass; and (5) soda-lime glass. The commercial ranges in composition of these types, as determined by analysis and calculation of oxide equivalents of the finished glasses, are given in Table 33-1, and the physical properties of some typical representatives of each type are given in Table 33-3.

Table 33-1

	Soda lime, per cent	Lead, per cent	Borosilicate, per cent	96 per cent silica, per cent	Fused quartz, per cent
SiO_2	70-75	53-67	73-82	96	99.8
Na_2O	12-18	5-10	3-10		
K_2O	0-1	1-10	0.4-1		
CaO	5-14	0-6	0-1		
PbO	....	20-40	0-10		
B_2O_3	....	.....	5-20	3	
Al_2O_3	0.5-1.5	.....	2-3		
MgO	0-4				

In other types of glasses such as colored, opal, and optical, the chemical composition is not the distinguishing characteristic, and they are usually made from the above types or "hybrids" thereof. Colored glasses are made by adding traces generally of metallic oxides to the batch, plus proper heat-treatment of the finished glass where needed. Opal glasses most often are made by adding fluorides or phosphates to the batch, and the finished glass is treated so that small particles appear in the body of otherwise transparent glass and cause the scattering light that makes opal glasses appear "milky." Optical glasses are made from a variety of compositions to get desired combinations of index of refraction and dispersive constant. Their distinguishing characteristic lies in the severe degree of freedom from physical imperfections required in the finished glasses.

---

[*] Superior numbers refer to specific references listed at the end of this section.

[†] ASTM C 162-45T.

There are a few nonsilicate glasses, *e.g.*, borate and phosphate glasses, made in small quantities for specialized uses.

PHYSICAL AND CHEMICAL PROPERTIES OF GLASSES

During recent decades industrial users of glass have adopted much more of an engineering approach towards its application, and glassmakers, through intensive research, have acquired scientific understanding and technical control of the material. New superior chemical types, particularly the low-expansion borosilicate glasses and 96 per cent silica glasses, have been developed. Technological improvements have been made in the old soda-lime and lead types, and designing and finishing treatments have been advanced greatly. The resulting improvements in mechanical strength, thermal endurance, chemical durability, and electrical properties have been so marked that glass, particularly of the low-expansion types, has gained wide recognition as a versatile engineering material.

In using the specific values for the various properties of glass listed in Table 33-3, it is necessary to keep in mind the following general comments because the physical nature of glass is so different from that of other engineering materials.

Mechanical Properties. Glass is a supercooled liquid and is not crystalline or endowed with any directional properties the way crystals are. It is nonductile and perfectly elastic; *i.e.*, it shows no cold flow right up to the stresses necessary to break it. It seems to be broken only by tensile stresses, the fracture starting in almost all cases from imperfections in the surface. It does not deform or decompose with aging or exposure to moisture, and it suffers no permanent deformation when subjected to mechanical or thermal stresses even at very low or quite high temperatures. Having no porosity whatever, it does not swell or shrink with changes of humidity or immersion.

1. *Strength.* For safe design practice, tensile stresses should be limited to 1,000 psi maximum for annealed articles and to 4,000 psi for tempered articles of glass. This is true since, although annealed articles have tensile strengths ranging from 4,000 to 10,000 psi and although many products can be tempered to have two to five times the strengths of annealed products, the evaluation of safety factors is rather difficult and depends upon the type of application and condition of the surface.

The nature of the surface has a great effect upon the tensile strength of glass. Not only are loading stresses considerably magnified in regions of surface imperfections, *e.g.*, scratches, but also the stress concentrations cannot be relieved by any yielding or cold flow since glass is nonductile. This results in the strengths of glass articles being markedly less than the 500,000 psi and upwards measured for some fibers of glass. It also results in noticeable variations in the measured strengths. Tempering puts a permanent compressive stress in the surface and thus strengthens a glass article and makes the glass more resistant to abrasion or scratching.

Glass tested in compression or shear seems always to be broken by the tension components of stress, and the terms compressive strength and shear strength are generally considered to have little meaning for glass. However, the apparent or effective compressive strength is about ten times as great as the normally measured tensile strength, and consequently it is a decided advantage, when using glass in conjunction with metals or other materials, to have the designs such that the forces on the glass are compressive rather than tensile. This is particularly true when temperature changes may introduce considerable stress in the glass because of differences in expansion coefficients.

2. *Moduli of Elasticity.* Young's modulus ranges from 6.5 × 10^6 to 12 × 10^6 psi for the various glasses. Poisson's ratio ranges from 0.18 to 0.30, but 0.22 may safely be used in design calculations.

3. *Hardness.* The nonductility of glass makes it difficult to assess the significance of indentation tests, and glass manufacturers use tests different from those used for metals. On the Moh scale of resistance to scratching, where diamond is arbitrarily assigned a figure of 10, glasses range from 5 to 7.

The terms "hard" and "soft" as used in the glass trade seldom refer to the mechanical hardness but rather to the question of whether a glass has a high or a low softening temperature, respectively.

Besides the Moh test, glass manufacturers sometimes use an impact-abrasion test in which the amounts of abrasion required for equal surface destruction are measured and calculated relative to that of regular polished plate glass. Assigning a figure of 1 arbitrarily to plate glass, the values for a few other types of glass are as listed in Table 33-2.

Table 33-2. Impact-abrasion Hardness

Plate glass (soda-lime glass)	1.0
High-lead glass	0.5
Borosilicate glass	3.0
96 per cent silica glass	3.5

Thermal Properties. 1. *Reference Temperatures.* Consonant with the fact that it is a supercooled liquid, glass has no critical temperatures. It has no freezing or melting point, and with change of temperature the viscosity changes continuously. The "melting temperature" of a glass is merely a high temperature at which the batch materials will fuse together and give a viscous, homogeneous liquid in a reasonable length of time. The viscosities of glasses are about 100 poises, even at the melting temperatures.

For the practical control of shaping and annealing operations, either in the glass factory or out in the field where the glass is being used, it has been found useful to define certain reference temperatures. The *softening* point[1] of a glass is the temperature at which a uniform fiber, about 0.75 mm in diameter and 22.9 cm long, elongates under its own weight at the rate of 1 mm per min when the upper 10 cm of its length is heated in a prescribed furnace at the rate of approximately 5°C per min. For glasses of density, about 2.5 grams per cc, *i.e.*, for all the commercial chemical types listed above, except the higher percentage lead glasses, this corresponds to a viscosity of 4.5 × 10^7 poises. The *annealing point* of a glass is the temperature at which internal stresses in the glass are substantially relieved in 15 min. It corresponds to the equilibrium temperature at which the glass has a viscosity of 2.5 × 10^{13} poises and is usually the high-temperature end of the annealing range. It is determined by a loaded-fiber method of measuring viscosity. The *strain point* is the temperature at which internal stresses in the glass are substantially relieved in about 16 hr and represents generally the low-temperature end of the annealing range for articles of ordinary thickness. Under conditions specified for laboratory tests, the viscosity at the strain point is 4.0 × 10^{14} poises. However, in cooling through the strain-point temperature, the properties have already begun to lag appreciably behind the temperature, and thus the viscosity reached in annealing practice may be appreciably greater or less than 4.0 × 10^{14} poises, depending upon the speed of cooling. It is for these reasons that the *maximum operating temperature* for annealed ware, if appreciable thermal and mechanical stresses are avoided, may approach the strain-point temperature, and there will be no danger of introducing appreciable permanent strain. For tempered ware the maximum operating temperature must be lower than the strain point if the mechanical strength is to be maintained at the higher level achieved by tempering.

2. *Linear Thermal-expansion Coefficient.* Coefficients of glasses range from values equal to and down to one-thirtieth those of metals. The values tabulated are averages for the range 0 to 300°C, but they differ little from the values for the range 20 to 80°C.

3. *Thermal Conductivity.* For different glasses the conductivities range from 0.0018 to 0.0033 or (gram-calories)(cm)/(sec)(sq cm)(°C). The conductivity at 250°C of a typical borosilicate glass is 20 to 25 per cent higher than its room-temperature value of 0.0028 gram-calories/(sec)(sq cm)[(°C)/(cm)], [0.0117 watts/(cm)(°C)]. Despite a lower thermal conductivity, glass dishes bake their contents faster than shiny metal dishes since glass reflects away so much less of the incident heat radiation. And because of the surface films that develop in service, heat exchangers made of metal turn out to be not much better than those made of glass.

4. *Thermal Endurance.* The ability to withstand, without cracking or breaking, rapid or uneven changes of temperature is called heat-shock resistance or thermal endurance. No general formula for the thermal endurance of glass articles has been found since it depends on all those complicated factors which control tensile strength as well as other factors. However, there are three useful generalizations: (*a*) the smaller the coefficient of thermal expansion, the greater the thermal endurance; (*b*) the thicker the glass, the more apt it is to break from thermal shock; and (*c*) glass will withstand a considerably greater total-immersion shock when heated than when cooled since in the first instance the surface is put into compression, while in the latter the surface is put into tension. Ordinary bottles are made of high-expansion soda-lime glasses, and they will usually break if plunged from boiling water into ice water, whereas most articles made of low-expansion borosilicate glasses usually will not crack even though some parts may be up to half an inch in thickness. The 96 per cent silica glasses do not crack even though plunged into ice water while they are at a glowing red heat.

Electrical Properties. 1. *Resistivity.* The volume resistivities of commercial glasses are so high, 10^8 to 10^{18} ohm-cm at room temperature, that it is difficult to make reliable measurements, and room-temperature values are available for only a small number of glasses. Generally, they are 10^{12} ohm-cm or higher. Since the resistivity of glass decreases appreciably as the temperature increases, it is more satisfactory to measure the resistivities of annealed samples at 250 and 350°C.

2. *Dielectric Strength.* The dielectric strengths of glasses in air range from 1,000 to 8,000 volts per mil of thickness and are so high that measurements are often made under dry oil to prevent "flashover." But under these conditions the oil generally fails first and sets up point electric stresses of extremely high magnitude with the result that only a fraction of the true dielectric strength of the glass is measured. Consequently, data taken under oil should be used only when the glass insulator is to be used under dry oil.

Corrosion Resistance and Chemical Durability. One of the most outstanding properties of glass is its great stability and chemical inertness. The resistance which it offers to the attack of water, to weathering, which is due primarily to water and carbon dioxide, and to the attack of aqueous solutions of acids (except hydrofluoric), bases, and salts is the main reason why glass is so widely used for the storage of foods, drugs, and chemicals; for chemical-laboratory ware; and for chemical-plant equipment such as containers, pipe lines, and pump parts. The *chemical durability* of glass is the lasting quality, both visible and chemical, of its surface. It is evaluated frequently, after prolonged weathering or storing, in terms of chemical and physical changes in the glass surface or in terms of changes in the contents of a vessel.

The chemical durability of a glass, considered as an intrinsic function of the glass, depends upon such factors as composition, thermal history, and surface treatment.

Today the demands upon the durability are becoming more and more severe because of using higher pressures, higher temperatures, and the like in the chemical industries. To meet these demands it is advantageous to choose a glass best fitted for the specific service, since, although the commercial glasses listed in Table 33-1 all have great chemical resistance in comparison to most all other materials, some have higher durabilities than others.

Some of the main factors which may affect the rate of attack of a reagent upon a glass are temperature, pressure, rate of agitation or flow of the reagent, and the nature of the reagent itself. Different glasses respond in different ways to these factors, and no accelerated (the normal rate of attack being too slow to measure in a reasonable

* Use in conjunction with preceding general remarks.
† For safe design practice, tensile stresses should not exceed 1,000 psi for annealed, and 2,000 to 4,000 for tempered glass depending upon piece in question.
‡ Approximate values.

length of time) laboratory test or practical series of tests has been devised to give a universal number for durability or to determine beforehand the durability for all service conditions. Results of accelerated laboratory tests must be used in combination with a background of actual service experience.

For general purposes, where high corrosion resistance is required, certain commercial borosilicate glasses and 96 per cent silica glass have wide application. They have excellent resistance to neutral solutions, to acids (except hydrofluoric), and to alkalies at moderate temperatures. Their low expansions make them valuable for chemical equipment where there are severe heating conditions to contend with. Their compositions are relatively simple, and this results in the contamination, if any, of the contents being limited to a few elements. For this reason they are suited to exacting chemical-analyses usage. This is especially true of 96 per cent silica glass which contains only traces of alkali elements.

WORKING CHARACTERISTICS

Cold glass cannot be turned in a lathe, surfaced in a shaper, or drilled with a machine. In other words, it cannot be shaped with a cutting tool. The drilling of small holes, a quarter of an inch in diameter or less, by triangular pieces of hard steel or carboloy, fed with turpentine and operated in a drill press, might be considered something of an exception. Larger holes can be made with a metal cylinder that has a serrated end, operated in a drill press and fed with a mixture of water and abrasive particles.

On the other hand, glass can be ground and lapped very much as can metals, except for slower speeds and extra mounting precautions. It can be polished to much smoother surfaces than can metals.

On the other hand, also, relatively large cylinders can be cut by a variety of simple "crack-off" methods. With the smaller sizes of rod or tubing a scratch with a diamond or a score with a carbide-wheel glass cutter allows the glass to be broken off squarely by putting the scratched region in tension. With thicker walled tubing, electrically heating a Nichrome wire placed in a scratch around the tubing and putting cold water on the scratched region is a more effective way of cracking off the tubing. Heavy pieces of glass can be sawed with abrasive wheels or diamond wheels.

Crews can be quickly trained to do pipe fitting of glass piping in the field with hot-wire crack-off and high-frequency electric sealing or welding.[2,3,4] For uses where service conditions do not require the standard conical glass flanged joint to be employed throughout the lines, a simpler method of field flanging has been developed. Known as pipe beading, the method consists of forming a bead by gas heating on the end of the desired length of piping. Considerably less equipment is needed than with electric sealing. The pipe-beading kits can be bought or rented at reasonable rates.

When glass is yellow hot, it is quite moldable and can be readily blown or pressed into complex shapes. A variety of mass-production methods exists for shaping hot glass as it emerges from the melting tank. Also cold glass can be reheated and then reshaped and welded. In the multiform process powdered glass can be cold-pressed or cold-cast to give articles that, after firing, are perfectly vitreous and vacuum-tight. Multiform articles can be of very intricate shape with holes, grooves, screw threads, and the like, and with some dimensions accurate to high precision.

FACTORS INFLUENCING CHOICE OF GLASS OVER OTHER MATERIALS

For many engineering uses the relatively low tensile strength and the limitations on cold working are disadvantages of glass. However, the toughness of most glass products today is such that the term "brittleness," in the lay sense of the word, is inappropriate, and modern glass is turning out to be strong enough for a great number and variety of new industrial uses. And the ease and speed of hot forming is a great advantage.

Also, the unique and excellent combinations of physical and chemical properties are great advantages. The most outstanding of its characteristics are

1. Transparency—very high and permanent.
2. Transluscency or opaqueness can be obtained as desired.

3. Allows very versatile control over the differential transmission or blocking of infrared, ultraviolet, or undesired parts of visible light.

4. Smoothness of molded surfaces or supersmoothness of ground and polished surfaces.

5. Good hardness and resistance to scratching.

6. Dimensional stability or permanence of shape is better than that of concrete or steel (hence the use of glass for the 20-ton 200-in. mirror disk for the Mount Palomar Observatory reflecting telescope). Glass is free from creep, from elastic hysteresis, and free from liability to permanent deformation under thermal or mechanical stresses.

7. Lightness, or low specific gravity.

8. Low heat conductivity as compared with metals. Yet, as discussed above, glass is suitable for a number of heat-transfer applications.

9. Very low expansion coefficients available in borosilicates or 96 per cent silica glasses.

10. Resistance to heat—good to excellent.

11. Resistance to heat shock, especially with the low-expansion types—good to excellent.

12. Small coefficient of reflection for radiant heat (see under thermal conductivity above).

13. Electrical insulation and dielectric properties—excellent.

14. Wide range of fine permanent colors.

PRINCIPAL TYPES OF INDUSTRIAL PRODUCTS

Chemical. In food- and drug-processing industries and in chemical industries, use is made for the most part of low-expansion, chemical, and heat-resistant glasses for:

1. Containers, tanks, jars
2. Piping and tubing
3. Centrifugal-pump parts
4. Laboratory apparatus
5. Tubing for heat exchangers
6. Cylinders for fractionating columns
7. Sight and gauge glasses
8. Godet wheels or pulleys for drawing rayon thread out of acid baths

Electrical and Electronic. In the electrical and electronic industries, glass is used for the following:

1. Insulators
2. Lightning-arrester bodies for power-line use
3. Ribbon-glass condensers
4. Fuse-plug bodies
5. X-ray-tube envelopes and X-ray absorbing sheet or molded shields
6. Electronic-tube envelopes and tubing
7. Mercury-switch envelopes
8. Metallized glass for containers hermetically sealed by ordinary soldering
9. Metallized-glass electronic components
10. Special glasses for matched expansion glass-metal fusion seals

Lighting. In the lighting industry glass is employed for the products listed below.

1. Incandescent-lamp envelopes, fluorescent-lamp tubing, sign-light tubing
2. Projection-lamp envelopes and cover lenses
3. Diffusing and lens-action prismatic light controlling glassware

Light Filters and Colored Signalware. In the field of light filters and colored signalware, glass is employed in the following materials:

1. Ultraviolet transmitting
    - *a.* Germicidal-lamp tubing
    - *b.* Sun-lamp bulbs
    - *c.* Black-light tubing
    - *d.* Bulbs
    - *e.* Filter sheets

2. Heat or infrared transmitting
    a. Heat-lamp bulbs
    b. Black-light vision filters
    c. Bulbs
    d. Tubing
3. Colored glass
    a. For signalware that often has accurate prismatic surfaces on cylindrical, flat, or lens shapes
    b. For filter sheets or covers

Thermal. In thermal installations, the materials listed below are made of glass.

1. Heat-exchanger tubing
2. Furnace windows
3. Induction-furnace crucibles and calcining jars and trays
4. Thermocouple protection tubes
5. Heat-absorbing sheet glass
6. Furnace cores or linings
7. Thermos- and Dewar-flask glass parts
8. Thermometer tubing
9. Heat-insulation Foamglas
10. Heat-insulation Fiberglas products
11. Heat-insulation double-glazed (sealed-in air space) windows

Optical. In the optical field, glass is used for the following:

1. Instrument lenses, prisms, and mirrors
2. Eyeglasses and goggles

Mechanical. Glass is used in the following materials in the mechanical field:

1. Jewel bearings for precision instruments
2. Optically flat surface plates
3. Machinists' gauges
4. Torsion fibers
5. Paraboloidal reflector shells for sealed-beam headlamps and projection lamps
6. Accurate-bore tubing for gas and liquid flowmeters
7. Blueprint cylinders and sheets
8. Molds for rubber and plastics
9. Diffusion vacuum pumps
10. Lubricator and oil cups
11. Rollers for yarns and thread
12. Fiberglas filters
13. Slide-valve disks for gas-meter valves and rotary-valve seats
14. Fiberglas textiles
15. Humidifier floats
16. Multiform glass pipe-line filters
17. Centrifuge containers
18. Level vials

Acoustical. In the acoustical field, glass is used for Fiberglas products for sound absorption.

Structural. In the structural field glass is used for the following:

1. Laminated safety-glass windshields
2. Tempered sheet for doors, machine windows, fire screens, backstops
3. Building blocks
4. Fiberglas-plastics board of very high strength-to-weight ratio
5. Cases and covers
6. Ultralow-expansion spacers
7. Mirror disks for ultraprecision reflecting telescopes
8. Foamglas floats

CARE AND MAINTENANCE OF GLASS EQUIPMENT

Recommendations for Handling and Installing. It has been found that workers handling and installing glass equipment tend automatically to be sufficiently careful.

Moreover, modern industrial glassware is more rugged and tougher than the glass products of five decades ago, and consequently, if properly installed, it has been found to give long years of trouble-free service under hard, continuous operation.

Nevertheless, since the tensile strength of glass is relatively low compared with that of steel; since assembly stresses cannot be relieved by any cold flow of the glass; and since deep scratches and sharp bruises may cause excessive stress concentrations when mechanical or thermal stresses occur later on, it may be worth while to list the following recommendations, no matter how obvious and natural some of them may be.

To avoid scratches, chipping, and sharp bruises, it is well not to unpack or unwrap glass equipment until the time of installation. Thus bumping against hard objects is avoided, and dirt, which sometimes may include abrasive particles, is kept away from the glass. Gaskets or pads of soft, resilient materials should not be exposed to picking up abrasive particles. Glass piping should not be racked along with steel piping, and rack pegs should be of wood or covered with rubber or friction tape if they are of metal. Hangars for glass piping should be padded with clean, soft, resilient material.

To prevent assembly stresses from exceeding the safe maximum tensile stress of 1,000 psi, it is well to check a number of installation details. In coupling flanged glass piping, gauge glasses, sight glasses, or the like, to metal parts, high point loading of the glass should be guarded against. The metal parts should be rugged enough not to deform under assembly stresses and should be flat and smooth. Resilient gaskets of materials and designs recommended by the glass manufacturer should be used. Nut, and bolts should be drawn up evenly and only tightly enough to prevent leakage. Stud and nut clearances should be sufficient but not greater than necessary. Moreover, since glass is appreciably stronger in compression than in tension, it is well to have coupling stresses on the glass compressive as much as possible. Good alignment is desirable at all times, and tanks, pumps, or other similar equipment to which glass piping is attached should be rigidly stationary so they cannot shift and put the glass under excessive stress. Hangers should be of recommended number, position, and alignment. Vibration in itself does not harm glass at all, but when piping is connected to vibrating equipment, the adjacent hanger should be located far enough away so that the displacements due to the vibration may be absorbed in the resilient gaskets at the flanged joints.

Inspection for strains in glass is simple with a polariscope and may be worth while.

Operating Recommendations. So as not to exceed the maximum safe tensile stress of glass piping in sizes up to 4 in. ID, it is recommended that pressures not exceed 50 psi. Pressures in the line should be checked or relief valves used, particularly with positive pumps, to protect against pressure surges. Closing valves too suddenly may cause excessive "water hammer" and vibration. Sometimes hydrostatic heads are sufficient to require allowance.

The maximum operating temperature depends greatly on whether the article is made of a high-expansion soda-lime glass or of a low-expansion borosilicate glass. With equipment made of borosilicate glasses of expansion coefficients around 35×10^{-7} per deg C, temperatures up to 220°F may be used freely in almost all cases, and higher temperatures—up to about 400°F are not uncommon. With the higher temperatures there might be thermal shock problems, and the glass manufacturer should be consulted. Pyrex-brand piping, which is made of a low-expansion borosilicate glass, will easily stand flushing with alternate cycles of cold water and live steam. Actually, Pyrex-brand industrial glassware does not have its strength measurably affected until the temperature reaches about 900°F, but the glass at a temperature over 400°F can be subjected to excessive thermal shock if it comes into contact with rain, cold-air blasts, and the like. Consultation should be made first with the glass manufacturer if such high-temperature service is contemplated.

Do not bring flames into direct contact with glass since some spots in the glass may be heated hot enough to introduce undesirable permanent strains.

Wooden guards may profitably be placed around glassware in regions of heavy traffic or around glassware outdoors that might have icicles fall on it.

Do not use wire brushes in cleaning glass. Cleaning can be accomplished often by flushing with cold or hot water. Acid solutions or hot 0.6 per cent alkaline detergent solutions containing a wetting agent may be used in various cases that are more obdurate.

Large glass vessels under gas pressure or vacuum should be caged for safety.

Alteration and Repair of Glass Equipment. Generally, alteration of glass equipment or the repair of cracked or broken articles out in the factory is not very feasible. A laboratory glass blower with the requisite knowledge, skill, and facilities can reform yellow-hot glass and properly anneal it if the article is not too large or of too great a wall thickness.

Recently, two methods have been developed for making alterations in glass piping installations made of Pyrex-brand piping. In both methods a stock length of flanged piping is cut with an electrically heated wire method of crack-off. Then in the first method[2,3,4] a glass flange is sealed to the cut end of the piping by high-frequency electric sealing or welding to give a flanged pipe of desired length. After the sealing, the weld is annealed by a small electric furnace that clamps around the pipe.

In the second method of field flanging or pipe fitting in the field, the cut end of the pipe is heated in a ring gas burner; and when the glass is soft enough, a beaded end is formed on the pipe by a rapid spinning of the pipe. The beaded end is annealed by rotating it in the same ring burner. Beaded piping can be joined to standard flanged piping or to other beaded piping. The beaded joint requires the use of rubber gaskets and is not ordinarily used for service pressures over 25 psi, for temperatures over 250°F, or for piping of inside diameter over 3 in.

GLASS SPECIALTIES AND THEIR CHARACTERISTICS

Building Blocks. Glass building blocks are hollow, partially evacuated blocks of variously figured transparent glass. They are used in buildings for non-load-bearing walls and partitions that give controlled "daylighting" combined with insulation against heat and cold, and insulation against noise.

Glass blocks are made by fusing together two halves of pressed clear glass, and thus the hollow space inside is completely and permanently sealed. The air pressure in the hollow is only about one-third an atmosphere, and hence a panel of blocks provides good thermal insulation. For example, the over-all coefficient of heat transfer, U value, is 0.49 Btu/(sq ft)(hr)(°F difference) for a 15-mph wind on the exterior of a panel.

The edges of the blocks are coated with a grit-bearing plastic material to ensure permanent and effective bond with portland-cement mortar in which the blocks are set. The crushing strength of panels so set varies from 400 to 600 psi for edgewise loading. Hence panels are self-supporting but should not bear any of the building load. Panels have a lateral strength or wind resistance of 55 psf for the maximum limit of 144 sq ft of unsupported area.

Owing to the different figurings of the surfaces obtained in the pressing, different patterns of blocks range from a high transluscency to a reasonable transparency and include prism light-directing and -diffusing patterns. In the diffusing units a screen of Fiberglas is sealed inside the block.

The blocks are available in three sizes: 5.75, 7.75, and 11.75 in. square in face dimension by 3⅞ in. in over-all thickness. Special shapes for corner pieces are made in 5.75- and 7.75-in. sizes, and special radial units for curved panels in 7.75-in. size.

Foamglas. Foamglas, made by the Pittsburgh-Corning Corporation, is a rigid material consisting of inert-gas bubbles completely encapsulated by glass. More than 5,000 bubbles per cu in. are formed in the foaming or cellulating of the glass by the evolution of internal gas at a high temperature. Foamglas is used for an easily installed industrial and commercial thermal insulation both in low-temperature and high-temperature applications. Also it is as good as or better than cork as a material for floats.

It retains its insulating property permanently since it is impervious to moisture, acid (except hydrofluoric and glacial phosphoric) atmospheres, vapors, and fumes. It does not pack, swell or shrink, slip, warp, or rot; and it is verminproof. Not only is it noncombustible, but it has resistance to heat and can be used at temperatures up to 800°F if thermal shocks are avoided.

Although it is friable to the extent that it crushes locally with point loading, *e.g.*, yielding to such surface irregularities as rivet heads and welds, it does not crack or break and will support its own weight permanently in any type of wall construction. It should not be used for load-bearing walls. The friability permits cutting and shaping Foamglas with ordinary tools.

The specific values of the physical properties of Foamglas are as shown in Table 33-4.

Table 33-4

Density	10.5 lb/cu ft (0.17 grams/cc)
Thermal conductivity, K,	
at 50°F	0.40 (Btu) (in.)/(hr)(sq ft)(°F)
at 300°F	0.55 (Btu)(in.)/(hr)(sq ft)(°F)
Expansion coefficient	0.000005 (in.)/(in.)(°F)
Specific heat	0.16 to 0.19 Btu/(lb)(°F).
Crushing strength	150 psi (average)
Modulus of rupture	90 psi (average)
Absorption (24-hr immersion in water)	2 percent by weight (average, all at surfaces)
Air infiltration of permeability	0
Capillarity . . .	0
Volume change with moisture	0

Standard sizes are slabs 12 by 18 in. of thicknesses 2, 3, 4, and 5 in and standard pipe insulation forms.

Double-glazed Windows. Double-glazed windows consist of two sheets of glass with an air space between. There are various types made with different kinds of spacers and sealing techniques. Their properties are approximately the same as those of glass blocks in insulating against heat and cold, reducing condensation on interior face, and in insulating against noise.

Heat-absorbing Glass. Heat-absorbing glass is made of both high-expansion and low-expansion compositions. These glasses contain certain metallic oxides which cause high absorption of infrared rays or heat waves. They are used in filters or windows to pass visible light while at the same time stopping appreciable amounts of the heat radiation, which causes unwanted heating, unwanted glare, and unwanted effects on fabrics, dyes, etc.

The low-expansion types, which are therefore heat resistant as well as heat absorbing, are about 85 per cent as transmitting for visible sunlight as ordinary sheet glass, while they exclude about 30 per cent of the solar-heat waves.

Heat-absorbing plate glass transmits less than 45 per cent of the solar heat, and at the same time more than 70 per cent of the total solar light. It is made of high-expansion glass (linear thermal-expansion coefficient 8.3×10^{-6} per deg C) and has a thermal endurance of 125°F. It is available in $\frac{1}{8}$-, $\frac{1}{4}$-, and $\frac{3}{8}$-in. thicknesses with plates ranging up to 10 by 18 ft for the $\frac{1}{8}$-in. thickness.

Tempered Plate Glass. Subjecting plate glass, after cutting, drilling, or fabricating in any way that is desired in the finished piece, to a heat-treatment or tempering puts a permanent compressive stress into its surfaces. This makes the glass tougher without impairing its other properties. It is four to five times stronger and will flex four to five times farther than normal annealed plate glass. It does not shatter into jagged splinters but rather falls apart into small, relatively blunt and harmless chunks. It is harder and more resistant to scratching. And it can be used at temperatures between 120 and 650°F. These improvements greatly broaden the field of use for plate glass.

NOTE: The tempered glass cannot be cut or drilled after tempering.

Tempered plate glass can be used for oven glazing, fire screens, fire windows where wired glass is not permitted by law, kick plates, all-glass doors, backstops at baseball fields and the like, as well as for many other applications that need tough windows.

It is available in $\frac{3}{16}$- to $1\frac{1}{4}$-in.-thick plates up to 48 by 108 in. in clear, colored, or colored-opaque glasses.

Pyrex-brand Piping.* The glass piping is made from borosilicate glass (properties listed in preceding material), which is mechanically tough and rugged, which has high resistance to heat and to heat shock, and which has high chemical-corrosion resistance. The piping conveys liquids and gases safely, visibly, and without contamination. Its low expansion coefficient makes possible the flushing of the line with alternate cycles of cold water and live steam, hot water, or hot detergent solutions for cleaning or sterilizing. It is quite resistant to pitting, and its "glass smoothness" facilitates cleaning and minimizes scale formation.

It is resistant to all acids (except hydrofluoric) and to alkalies. Frequently it is used to handle hydrochloric acid, nitric acid, wet chlorine, bromine, chromic acid, chlorinated hydrocarbons, brine, organic acids, pharmaceuticals, sensitive drugs, and wine.

Piping is made with conical flanged ends, and with standard fittings and gaskets stocked by the glass manufacturer, it is possible to join lengths together and couple to metal flanges. It is available with 1-, 1½-, 2-, 3-, and 4-in. ID sizes in standard 10-ft lengths. Other lengths are made to the purchaser's designs, and while it is unusual to use pieces over 10 ft, it is not impractical to use lengths up to 15 ft.

Some Other Pyrex-brand Industrial Glassware of Borosilicate Glass. Tubing of the same glass used in making piping is available in a wide range of sizes for use in manufacturing laboratory equipment, tapered flowmeters, heat-exchanger tubes, and many miscellaneous pieces of plant equipment. Ranges of diameters extend from ¼ to 4½ in. in intervals of ¼ to ½ in. Wall thicknesses range from 1/16 in. for the small sizes up to ¼ in. for the heavier pieces. During the Second World War the drawing machines were equipped to make tubes up to 6½ in. OD and in lengths up to 6 ft. These larger sizes are made to order and are not ordinarily stocked.

The tubing can be of elliptical cross section, rather than circular, for special applications such as cell cooling coils.

Tube and shell heat exchangers can be equipped with thin-wall glass tubes if the end sheets are designed to hold a packing that permits the glass tubes to move slightly with respect to the shell. A number of successful heat exchangers of this type use rubber O rings.

Borosilicate hand-blown glass cylinders are made in sizes from 5 in. OD up to 23½ in. OD. Table 33-5 lists the sizes and lengths most frequently produced.

Table 33-5. Frequently Used Sizes of Borosilicate-glass Cylinders

Outside diam, in.	Nominal wall thickness, in.	Max length, in
7	1/8–1/4	24
8	1/8–1/4	16
9⅛	3/16–3/8	24
10	3/16–3/8	20
11	3/16–3/8	19
12	3/16 1/2	24
13	3/16–1/2	23
14¼	3/16–1/2	28
16	3/16–1/2	24

Large cylinders are often used to make observation sections in pilot-plant fractionating columns. Entire fractionating columns can be built with glass cylinders when chemical attack is exceptionally severe or when reactions can be accelerated by the admission of visible light and near ultraviolet

Flat-bottomed borosilicate-glass jars are available in sizes as large as 16 in. OD by 36 in. long and 18 in. OD and 18 in. long. They have been much used for the bodies of electrolytic cells because they are much less vulnerable to temperature stresses than other ceramic containers of the same size.

---

* Pyrex and Vycor are registered trademarks of Corning Glass Works. Their sole function is to indicate the origin with Corning of the products on which they appear. A large number of different glass compositions, varying widely in physical and chemical properties are used in the fabrication of glassware and sold under both trade-marks. The Pyrex trade-mark is also applied to certain metal articles.

Borosilicate plate glass is available in thicknesses of 3/16, ¼, and ⅜ in., and ½-in. thicknesses are planned for. Sheets are normally smaller than 24 by 30 in., but it is possible by special order to obtain sheets as large as 24 by 60 in. Applications include low-pressure sight glasses, furnace- and oven-door glasses, and occasionally such unusual purposes as crane cab windows in steel mills. Molded sheets and slabs of borosilicate glass are made in thicknesses up to ¼ in. These heavier pieces are ground flat and polished for use as sight glasses in pressure vessels.

Molded sight glasses are made in several standard sizes ranging from 2½- to 8-in. diameter for low-pressure service and from 4- to 8⅜-in. diameter for pressures ranging between 150 psi for the former and 30 psi for the latter. When necessary, these glasses can be strengthened by tempering to double their maximum safe working pressures.

Molded borosilicate godet wheels are used in the viscose-rayon industry to draw wet fibers out of the acid baths. Glass is used for this purpose because of its corrosion resistance and its smooth abrasion-resistant surface which requires no finishing operations subsequent to molding. Intricate glass parts for a centrifugal pump are molded and then ground so that impeller, volute, head plate, and seal ring fit together in such a way that chemicals flowing through the pump do not come into any contact with metal.

Products Made of Glass Fibers. Glass in the form of fibers is a new basic engineering material. Fiberglas fibers, made by the Owens-Corning Fiberglas Corporation, are produced in a wide range of diameters and of various glass compositions fitted for specific types of application. The range of diameters is from coarse (0.010 in.) through fine textile (0.00022 in.) down to superfine (0.00009 to 0.00005 in.). The fibers are solid rods of glass and possess most of the good properties of ordinary forms of glass:

1. Noncombustibility and high resistance to heat
2. Nonporosity; hence nonhydroscopic and do not shrink, swell, and stretch
3. Chemical resistance to weathering, acids, oils, corrosive vapors
4. Nonductility
5. Inorganic in composition and hence rotproof, mildew-proof, as well as waterproof. Also immune to attack of insects, rodents, and other vermin
6. Excellent electric-insulation properties
7. Possess no odor and do not pick up odors

Because of their fineness, the fibers possess in addition such new and very desirable properties as

8. Great flexibility
9. Great tensile strengths, ranging up to 250,000 psi, and possessing greatest tensile-strength–weight ratio of any commercial material

The Fiberglas fibers are used in more than 100 Fiberglas products which are derived from four basic forms. All the forms are incombustible, nonabsorbent of moisture, not subject to rot or decay, resistant to most chemicals, and provide no sustenance for insects and vermin. The four basic forms and their properties and primary uses are as follows:

1. Wool forms
   - *a.* Light weight: 1 to 9 lb per cu ft
   - *b.* Operating-temperature range for thermal insulation use: subzero up to 1000°F
   - *c.* Thermal-insulation value: K, 0.25 to 0.30 (Btu)(in.)/(hr)(sq ft)(°F) at various densities, at 70°F mean temperature
   - *d.* Sound absorption: high noise-reduction coefficient at various densities, thicknesses, and finishes
2. Filter and aeration forms
   - *a.* Air filtration: standard 1- and 2-in. thicknesses of fibers covered with special dust-catching adhesive provide highly effective method for cleaning air of dust, lint, and pollen

  - *b.* Industrial aeration packs: semirigid packs of bonded coarse, medium, or fine fibers used to filter air of gases, liquids, sludges, etc., and in contact and eliminator applications where water is used for cooling, humidity control, or air washing. Tower packing is used in petroleum, chemical, and distillery industries for evaporation, absorption, and fractionation applications where surface area of liquids must be greatly increased or gases are to be absorbed

3. Textile forms
   - *a.* Limited stretch, nonswelling or shrinking, low expansion coefficients, and high strength-weight ratios
   - *b.* Electrical insulation: excellent insulation characteristics in cloths, tapes, cordage, braided sleevings; varnished cloths, tapes, and tubing; combination Fiberglas-and-mica sheets and tapes; laminated-Fiberglas sheets, sticks, or wedges; Fiberglas-covered wire. Such forms impregnated with silicone resins make possible great improvements in electric-motor construction—light weights, smaller motors, and ability to stand severe overloads
   - *c.* Industrial textiles: noncombustible and heat resistant
   - *d.* Reinforcement in laminates, plastics, etc.
   - *e.* Chemical filtration
4. Mat forms
   - *a.* Storage-battery retainer mats
   - *b.* Acoustical surfacing
   - *c.* Filtration
   - *d.* Reinforcement for electrical insulating plastics
   - *e.* Pipe wrapping

PLASTICS

BY GEORGE K. SCRIBNER

President, Boonton Molding Company

INTRODUCTION

Plastics are synthetic materials put together by the ingenuity of the laboratory for the explicit purpose of assembling qualities and economies of manufacture not available in natural materials. When the modern age of plastics began with the discovery by Dr. Leo H. Baekeland in the early 1900's of a practical way of utilizing the long-known reaction between phenol and formaldehyde, plastics were first thought of as substitutes for other materials of engineering.

Plastic chemistry usually starts with so-called intermediates. Acetylene, acetone, phenol, formaldehyde, benzene, and many similar compounds are diverted, split apart, and recombined to form elementary plastics. These are still not the plastics seen and used by the consumer. They must be converted to such a stage by a combination of mechanical and chemical processes.

The plastics industry, in diagram, is somewhat similar to a tree. The trunk is made up of a large number of large chemical companies who process the basic raw materials into usable and, as yet, raw compounds. The roots literally absorb from the ground the starting materials, the carbon, hydrogen, oxygen, and nitrogen. Other constituents come from water, air, coal, oil, and miscellaneous natural compounds. All these materials pass up the trunk and are there transformed by chemical and research groups into the secondary usable plastics which are then ready for pressing, mixing, and fabrication into a multitude of products.

When these raw plastics are ready, they are usually sold by the chemical companies to specialists in paint, lacquer, safety glass, paper, novelties, general moldings, plywood, and many other industries. These specialists fabricate the article which is finally seen and used.

PLASTICS CLASSIFICATIONS

Plastics are classified in several ways. The most important division that covers the entire field is by a behavior pattern.

Thermoplastics are those plastics which soften under heat and again harden when cooled. No internal chemical change takes place. They are very like paraffin in this respect. There are roughly 14 basic materials in this group with a softening point ranging from 140 to 220°F. They will vary greatly in their mechanical and electrical qualities within the range of their optimum operating temperature. Some have excellent qualities all the way down to −60°F. Some have a sharp softening point, while some get progressively softer as the temperature approaches the deadline.

Thermosettings will soften only once under heat and then undergo an internal chemical change which makes them hard and impervious to further applications of heat up to the charring or disintegration point, which ranges from 250 to 300°F. There are only three of these plastics in current use, phenol formaldehyde, urea formaldehyde, and melamine formaldehyde, all familiarly called by their first names, phenolics, ureas, and melamines.

Plastics are again classified by their chemical composition into the following general groups:

1. *Thermosetting resins*
   a. Phenolics
   b. Ureas
   c. Melamines
2. *Thermoplastic resins*
   a. Styrene
   b. Acrylics
   c. Polyamides
   d. Polyethylene
   e. Vinylidene chloride
   f. Vinyls
3. *Cellulosics*
   a. Acetate
   b. Butyrate
   c. Propionate
   d. Ethyl
   e. Nitrate
4. *Naturals*
   a. Casein
   b. Lignin
   c. Shellac
   d. Cold-molded

COMPARISON OF PLASTICS

Each of the various plastic materials has its own outstanding field.

The most universal is molded phenolic. It may be outdone in cheapness at times by shellac and cold molded, but only at a sacrifice of strength and appearance. It is outdone in appearance by cast phenolic, urea, melamine, cellulose acetate, acrylate, and styrene.

The thermosetting resins, of which phenolics are the outstanding example, are made up of roughly half binder, the resin itself, and half filler. This allows a wide latitude of characteristics depending on the filler used. The cheapest of the group has wood flour as a filler. This is not only the simplest to make into intricate shapes but has a pleasing, smooth texture. The filler can be changed to cotton flock to get more strength and still maintain the nice surface. Chopped canvas gives more strength according to the size of the particles used. Asbestos filler gives higher resistance to heat and a better water resistance. Mica adds materially to the electrical qualities. Any choice between these materials probably means a compromise between cost and the qualities desired in the end product.

Ureas are based on a water-white resin and therefore give a depth of surface and translucency which affords them a marked advantage in any article in which eye appeal is a factor. They are more expensive to produce both because of the pastel shades in which they commonly appear and the higher cost resin used. Although their appearance can be duplicated in some of the thermoplastics, the fact that they are no longer affected by heat within the range of their operating temperatures in many cases make their use necessary.

Melamines are comparatively new to this group since their commercial development took place during the Second World War. They were popular with the armed services because of their heat resistance, low water absorption, strength, and the fact that they would not sustain an arc at high altitudes.

Cellulose acetate is employed primarily for appearance and secondarily for strength. Where ordinary room temperatures are involved and no undue mechanical strain comes on the piece, it will perform excellently. Since it is a thermoplastic, there is a certain element of cold flow. The raw material is fairly high in cost, but this can often be made up by the advantages inherent in the basic method of shaping, *viz.*, injection. The larger the piece, the less chance there is of making it at a price competitive with the cheaper materials.

Cast phenolics are among the most beautiful of the plastics. They offer a wide range of color, depth of surface, and even variegation of internal appearance. They are expensive in most shapes for the very reason that they are cast. They must be machined at the gate line, which is usually one whole surface. Cast phenolics are an exception to almost everything that has been said about plastics to this point. They are made in their raw state, a liquid.

Laminated phenolics and ureas have a broad field. Their ability to reproduce on their surface almost anything that can be printed on paper permits them to imitate wood, marble, onyx, or any other material commonly used for facing. Developments have brought out surface decorations that cannot be duplicated by any natural product, and like all plastics they are being accepted in their own right and not for imitative purposes. Their extreme strength and easy tooling in simple forms fit them into increasingly wider fields.

Acrylics have excellent optical qualities in the transparents and are outstandingly beautiful in colors. They are the most expensive of the eye-appeal thermoplastics and have a depth of surface that makes them very attractive in many applications.

Styrene is the cheapest of the thermoplastics on a cubic basis because of its comparatively low price per pound and its low specific gravity. Its surface tends to meet the eye like a sharply varnished article. It tends to be brittle, although not seriously so. Some chemicals will cause it to craze, but on the whole it has a high reputation for its chemical and water resistance. It definitely has outstanding electrical qualities at high frequencies.

Cellulose nitrate is not moldable. It is made up in sheets, rods, and tubes and must be machined to the desired form. Because of its excellent tooling qualities, this is not difficult. It is strong, but tends to become brittle with age and is flammable.

Cold-molded can be highest in heat resistance of any of the plastics if a cement-base material is used. However, the general classification also includes bitumen or asphalt binder, which is definitely a low-temperature material. The cement-base cold molded is used for such applications as electric-stove heating-coil holders; the bitumen base is indicated for inside electrical parts where appearance is of no importance. Strength is not one of its outstanding qualities.

The vinyls comprise one of the newest, best known, and most versatile families in the plastic group. Although some of them are molding compounds producing rigid pieces, it is as rubbery, often transparent, materials that the group is best known to the public. These materials usually have excellent water and chemical resistance, so that they have become valuable as replacements for rubber not only to the public but also for industry. They are important as coatings for other materials, especially textiles and paper.

Polyamides, although a large family capable of many variations in characteristics, are so far represented only by nylon. This same material prepared in granule form makes excellent moldings having great strength in small cross sections. It has the highest heat resistance of the thermoplastics and a very sudden softening curve. It is also the highest priced molding material in its raw form.

Vinylidene chloride is most widely used as monofilaments and tubing. Some molding is done, but because it is sensitive under the heat of molding, having a tendency to throw off hydrochloric acid in the molding machine, it requires special metals for heating chambers and careful handling. This characteristic does not extend to the material after molding.

Casein, a product of cow's milk, can be made only in sheets and rods from which it must be machined. Its principal use is in buttons.

Lignin is present as the binder in nature, holding together the cellulose in plants. As a plastic binder it has intrigued the chemists for years, but so far they have not been able to extract it in sufficiently uniform composition to be practical for general molding. It is widely used in wallboard and similar flat sections.

Shellac is one of the oldest plastics. It is a natural gum produced by insects and is subject to all the variations of quality and end characteristics found in natural products.

PLASTICS MATERIALS

Phenolic-base Compounds. Phenol, commonly called carbolic acid, is obtained from coal tar and is produced in the form of white crystals. It readily liquefies when heated or may be obtained in liquid form produced by the slight addition of water.

Formaldehyde is made by passing heated wood alcohol mixed with air over heated copper or platinum, causing partial oxidation. The resulting product is a gas, and for commercial purposes it is dissolved in water. This solution is commonly called Formalin.

Under carefully controlled conditions these two materials are blended to form a resin which has the valuable characteristic of softening under the application of moderate heat and very shortly hardening into an infusible mass. This characteristic is called "heat irreversibility."

This resin is combined in varying percentages with many different fillers such as wood flour, asbestos, fabric, graphite, paper, and many others so as to obtain the added value given by the distinctive properties of these materials: better molding qualities, greater toughness and strength, and more resistance to heat.

The chemical reaction, known as the "cure," requires from 45 sec to 12 min depending on the particular class of compound used and the shape and size of the piece in question. Practically all modern phenolics are removed from the mold without reduction of temperature, although in some cases cooling is used in an attempt to freeze an exceptionally smooth and lustrous surface.

These materials burn very reluctantly. Age has no effect, but sunlight will discolor the lighter shades. Weak acids, reducing acids, and organic acids have little or no effect. Strong oxidizing acids decompose them.

Weak alkalies have a slight effect, while strong alkalies decompose them. Organic solvents have no effect when bleedproof materials are used. Organic solvents do not affect moldable transparents and cast phenolics.

Phenolic molding compounds are generally classified by their filler as follows:

1. Cellulose filled, general purpose
2. Flock filled, medium impact
3. Chopped-fabric filled, impact
4. Asbestos filled, heat and water resistance
5. Resin filled, moldable transparent
6. Special purpose

Industrial Resins. At the present time various industrial resins are finding wide use in the manufacture of resinoid grinding wheels, brake linings, thermal-insulation bolts, electrical and structural laminates, plywood surfacing papers, lamp-basing cements, plywood adhesives, sealants, and miscellaneous adhesives.

Phenol-furfural Resins. Most of the progress in the use of phenol-furfural resins and molding compounds has been made in transfer, injection, and low-pressure molding of these materials, whose set time and flow characteristics are well suited for these forming processes.

It has recently been shown that by adding of resins made with furfural and amines, phenol, etc., to wet aggregate before it is mixed with bituminous road surfacing reduces the tendency of the aggregate to strip. The same property makes it suitable for roofs, airplane runways, and other load-bearing surfaces. This product is suitable for combination with soil as well as aggregate.

The main source of furfural is waste farm products such as oat and rice hulls, corncobs, and cottonseed hulls, all of which are rich in pentosans. These raw materials are digested with an acid, such as sulfuric acid, to yield furfural.

Furan Resins. The outstanding characteristics of furan resins to date appear to be their penetrating ability as liquid-impregnating compounds, their chemical resistance as surfacing agents, and their bonding strength as adhesives. Furan derivatives form thermosetting plastics which resemble phenolics in physical properties but which bear no chemical resemblance to this group of compounds.

The most widely used raw materials in the manufacture of furan resins are furfuraldehyde and furfuryl alcohol. The furan ring has long been recognized as capable of self-polymerization under the influence of strong acid catalysts.

Furan-resin adhesives have now been established successfully in several important lines. Furan-impregnated plasters offer superior strength and durability, which were unheard of in gypsum plastics before their treatment with resins. Surface coatings of furan-resin derivatives are now being manufactured by several different companies. Liquid furan resins are also available for casting purposes.

Some trade names for furan resins are Plaspreg, Resin X compounds, Duralon, and Furetone.

Aniline-formaldehyde Resins. Resins made with diphenylamine serve a definite industrial need. They are fusible but cure rapidly at 265 to 320°F under pressure to form hard products of high softening point.

Aniline-formaldehyde resins can with proper care be machined; the electrical properties are little changed by plasticization, and the cold flow of the unplasticized grade is very slight. Ultraviolet rays and weather do not affect this material. It has a low power factor, dielectric constant, and loss factor, all of which are remarkably stable over an extremely wide range of frequencies and in the face of the most adverse moisture conditions. Its dielectric strength is high.

It has noteworthy resistance to alkalies and is not soluble in any of the common organic solvents. Its resistance to gasoline, aromatic hydrocarbons, acetone, and alcohol is excellent.

Aniline-formaldehyde resins are available in impregnating varnishes, sheets, and rods.

Resorcinol-formaldehyde resins are outstanding for use in gluing exterior plywood and for assembly work requiring high water resistance. They are particularly suitable for the assembly of boats and sections for prefabricated houses. They are appropriate for bonding wood, leather, plastics, and a variety of materials to other surfaces.

Mass production of fine wood assemblies has been facilitated and rendered less expensive through the use of a special grade of resorcinol resin. As many as six operations can be eliminated from the assembly of a molded-plywood radio cabinet in which the resin has been employed. Moreover, the assembly is resistant to warping and delamination.

The most important characteristic of resorcinol resins is their ability to react at temperatures of 75 to 90°F within controlled time periods of several minutes to several hours. Also characteristic of these resins is their excellent compatability with many other plastics and elastomers. In general, improved water and heat resistance result from such combinations.

Resorcinol resins and copolymer resorcinol-phenol resins are available as solids and in various solvents. The solid resins are generally two stage, requiring an added setting agent before use.

Resorcinol glues are the only low-temperature glues providing maximum resistance to exposure. Because of their high affinity for wood, the most important application of these resin adhesives has been in wood gluing, both in laminating and molding. Some trade names for these resins are Amberlite, Bakelite Resorcinol-formaldehyde, Cascophen, Durez, Durite, Lauxite, Penacolite, Phenac, Plyophen, and Taccalin.

Phenolic Sisal. In phenolic sisal long sisal fibers are worked into a fluffy batting which in turn is mechanically reduced to a firm feltlike blanket. This blanket is impregnated with resin, and powdered resin is sometimes vibrated into its interstices.

Alkyd Resins. Alkyd resins comprise a useful class of synthetic polymeric materials generally defined as reaction products of polybasic acids or anhydrides and polyhydric alcohols.

Alkyds based on maleic anhydride, when used with some of the newer types of varnish oils, produce varnishes which have outstanding characteristics of durability and high resistance to alkalies. They also dry rapidly. According to end use, the resins are generally divided into two categories—the varnish type and the lacquer type. The varnish type is widely used as a vehicle for metal decorating, household utility varnishes, and architectural white-enamel vehicles. The lacquer-type maleic resins are usually dissolved in solvents and used with cellulose nitrate in the production of lacquers.

Alkyds based on sebacic acid and other high-molecular-weight aliphatic polybasic acids have been used with polyvinyl chloride and its copolymers. They are used in fabric coatings of all types. Typical examples are raincoat, upholstery, and bookcloth fabrics. They are also used in rubber and cable lacquers of all kinds.

Trade names for the phthalic alkyd resins are Amberlac, Aroplaz, Beckosol, Dulux, Duraplex, Dyal, Esterol, Falkyd, Glyptal, Mirasol, Rezyl, and Syntex; for the maleic alkyd resins, Amberol, Arochem, Beckasite, Carbic and C-9, Dulux, Dymal, Lewisol, Paranol, Pentalyn, Petrex, and Teglac; for sebacic and others, Paraplex.

Polyester Resins. The polyester resins constitute a large and useful family of resins based on acids, alcohols or glycols, and unsaturated hydrocarbons. The combinations and permutations seem to be endless, and most of them have very valuable qualities. They are available in liquid or semisolid resin form, cast sheets, rods, and tubes. The outstanding qualities offered are chemical resistance, dielectric properties, low water absorption, low-temperature cure, toughness, low-pressure or contact cure.

Trade names of polyester resins are Bakelite Polyester Resins, Kriston, Laminac, MR-Resins, Paraplex, Plaskon, Selectron, Thalid, and Vibrin.

Phenolic-base Compounds—Laminated. The fundamental difference between laminated and molded phenolics is in the nature of the filler used. The resin is basically the same, although in the molded group, it has been developed along the lines of speed of cure, a characteristic which is not so important in the laminated industry. Molded phenolics are powders or comparatively small pieces impregnated with resin. Laminated uses sheets of paper, linen, canvas, and silk, impregnated and dried in a continuous operation, so the original interlacing and length of fiber are not destroyed. The trade has standardized on grades which, by variation of the filler and treatment, have different qualities. Like molded phenolics, if one characteristic is to be emphasized, others may have to be minimized. The strength, flexibility, and imperviousness to oil and moisture are the outstanding qualities that suit this material for its wide use as silent gears. These are hobbed from molded or cut blanks. Its high dielectric strength, high insulation resistance, and great strength in thin sections recommend it for simple punchings. It is widely used in the plating industry in place of wood for barrels and carriers. The rayon industry uses it not only because it resists alkaline reagents but because of its lightness and strength.

Manufacturers of laminated material of this type affiliated with the National Electrical Manufacturers' Association have adopted a common nomenclature in describing their sheets as follows:

Grade X—for general use. It has a paper base furnished in natural, chocolate brown, and black with natural core. Thicknesses are from 0.015 in. and up. It punches up to 1/32 in. cold and to greater thicknesses when heated and machines readily.

Grade XX—for electrical applications requiring low moisture absorption. It has a paper base in natural or black. Thicknesses are from 0.015 in. up. It has low moisture absorption.

Grade XXX—for extremely low moisture absorption and high dielectric strength. It has a paper base, natural or black. Thicknesses are from 1/32 in. up.

Grade XP—for punching operations and electrical applications. It has a paper base and comes in natural, or chocolate brown with natural core, black with natural core, black with black core, and chocolate brown with shiny or satin finish. It punches and shears cold up to 3/32 in. and in thicker sections depending on the design of the die and the temperature of the material.

Grade C—for exceptional structural strength. It has a canvas base and comes in natural or black. It punches readily and makes highly resilient insulation. Its structural qualities recommend it where high tensile and transverse strength are required in connection with good insulating properties.

Grade L—for fine machining. It has a linen base in natural or black. Thicknesses are from 0.015 in. up. It is not usually required over 1/8 in.

Different manufacturers produce minor variations of the above general classifications to suit their individual customers' requirements and in some cases have prefixed or suffixed the above symbols with symbols of their own. The price varies with the resin content although not in direct ratio.

Tubes are produced in two grades, wrapped and molded.

The essential difference between wrapped and molded is principally in their physical characteristics. Molded is naturally more dense and less water-absorbent. The wrapped tube is, however, the more resilient. Also, the wrapped tube, properly made, is a more reliable dielectric for high voltage.

Postforming of Laminated Phenolics. Laminated phenolic was for many years believed to be virtually inert at temperatures below decomposition. Recently there has been developed a line of hot-forming laminated plastics which, when heated rapidly to a temperature of about 275°F, pass through a stage of considerable flexibility and, when cooled to ordinary temperatures, recover their average physical properties.

Phenolic-base Compounds—Cast. The ingredients of cast phenolic-base compounds, of which there are several well-known makes, are essentially the same as the phenol-formaldehyde molding resins. The difference is that they do not contain any filler and are cast in lead molds instead of being molded under pressure in steel dies. Castings can be purchased in stock forms such as sheets, rods, and tubes. Special castings such as cutlery handles, gear-shift knobs, handles of various types and designs, clock cases, and any item that does not require a split mold can be made. Sheets are of $\frac{3}{32}$ in. minimum thickness. The material in its finished form is nonflammable, odorless, tasteless, and possesses high dielectric strength. Sanding is done on equipment like that used for wood, and a standard buffing wheel is used for polishing.

These resins may be bent or formed to shape by immersing them in hot oil at 250°F for a short time, varying with the thickness, then placing them in a form and cooling. They may be stamped, embossed, engraved, or carved. They can be heated and shrunk on metal shafts such as cutlery handles on metal tangs. They can be machined to close tolerances, the shrinkage and expansion being so minute as to be negligible. Age slightly increases the hardness of the material and improves the electrical properties. Sunlight yellows and fades nonfast colors. Weak acids have no effect, but strong acids slowly attack it. The material can be washed with soap or soap powders. It slowly softens when immersed in alkaline solutions, showing slight discoloration. Strong alkalies will attack it slowly. It is insoluble in alcohols but shows slight swelling in ethyl alcohol after long immersion. It is unaffected by ketones, esters, hydrocarbons, mineral, animal, or vegetable oils; insoluble in water, organic solvents, and acids; slightly soluble in alkalies.

This material is probably the most beautiful of all the plastics when proper finish is applied. It has a luster and depth that cannot be approached, and its fine-flowing qualities as it is poured into the mold give effects very closely resembling minerals and precious stones. It is available in translucent, transparent, or opaque forms. The very definite limits on the application of this material come from the fact that it is cast only roughly and not pressed. The comparison is similar to that of a cast-iron part with a pressed-steel piece.

Urea-base Compounds—Molded. Urea molding compounds are well established in the field of commercial plastics molding and offer certain outstanding advantages. They are thermosetting: *i.e.*, while being molded under heat and pressure, a chemical reaction occurs which makes the finished molded piece resistant to further applications of heat.

The chief appeal of these moldings lies in the beautiful color effects obtainable, and in addition, the finished moldings are odorless and tasteless. Unlike the colored phenolic compounds, the molded urea resins can be made with a considerable degree of translucency giving a brightness and depth of color somewhat similar, although superior, to opal glass.

The urea resins are much more expensive than the ordinary black phenolic compositions. There is an additional cost during the molding operation owing to the great care that must be taken in keeping the moldings free from foreign matter. Such small defects do not appear on the surface of black and darker colored moldings.

Colors. Urea is produced in all colors from translucent colorless to natural and white and lustrous black. There is a list of standard colors, however, which carries a price somewhat lower than specials. It is better to use one of the standards wherever possible, although any shades can be matched. This price differential applies only to quantities less than 3,000 lb. Some tints, such as orchid and pink, are very difficult for the molder to control.

Light has no effect on red, natural, gray, green, blue, and black urea compounds. It has a slight effect on orange, yellow, ivory, and coral. Pink and orchid fade badly on exposure to light. These effects are subject to variation between the light and dark shades of each color.

Water Absorption. Molding of the urea-resin type shows a certain amount of water absorption. Nevertheless, these resins will withstand a great deal of service in contact with water without deterioration. The leading manufacturers claim that they will withstand short immersion in boiling water without deleterious effect.

Heat. Urea-formaldehyde moldings are noninflammable but char at about 200°C. They are not, therefore, suitable for such articles as ash trays, etc. Tests show that temperatures from −10 to +175°F have no effect, but higher temperatures over prolonged periods will cause fading and eventual blistering.

The intermediate water-soluble products are starting materials for the production of resin adhesives, surface coatings, paper conditioners, and other special items, all of which are finally cured through heat and catalysts. The resin is currently being applied in the production of toweling, blueprint, tag stocks, map, and chart papers, bag and wrapping papers, glassine and greaseproof papers, tissue papers, and manual and book papers.

The resin may be used as the principal bonding materials for laminated sheets. In laminates which are bonded by other materials, urea resins are sometimes employed only on surface laminae for color effects. Urea resin is also used as a binder in the making of sand foundry cores. As an adhesive it has been found suitable for edge gluing of lumber cores and various wood articles. One resin has been developed for use in conjunction with starch as an adhesive in the manufacture of fiber containers.

Urea-base compounds were approved by the Underwriters' Laboratories, Inc., as "acceptable for use in electrical devices and for the mounting of current-carrying parts," Mar. 28, 1932.

Melamine-base Compounds—Molded. Melamine (introduced in this country in 1939) is one of the most recent additions to the plastics industry. It bears a close relation to the compound calcium cyanamide and is produced from that compound by the initial production of dicyandiamide. Melamine is considered as a trimer of cyanamide CH_2N_2 of which dicyandiamide is the dimer.

Melamine, in combination with formaldehyde as a resin, may be combined with various fillers to form molding compounds. In combination with an alpha-cellulose filler the melamine molding compound has much the appearance of urea-formaldehyde compounds but has superior heat, water, and chemical resistance. It is odorless and tasteless. In combination with a mineral filler such as asbestos, it has the highest arc resistance of any synthetic molding compound and has high dielectric strength, dimensional stability, and low moisture absorption. In combination with chopped cotton rags, the melamine resin has high flexural strength, will absorb considerable shock, has a fairly good arc resistance, but will not support combustion. When combined with urea formaldehyde, melamine provides an adhesive producing a bond which withstands boiling water. These resins can be used in the production of laminated plastics at pressures as low as 30 psi. Numerous special applications of the resin include beater treatment of paper for wet strength, nonshrink treatment of cottons and woolens, tanning of leather, and a variety of coatings.

Styrenes. Although styrenes have been commercially available in the United States since 1937, it is only in the last few years that polystyrene has become widely popular. Its electrical properties remain nearly constant over a wide range of frequencies, temperatures, and humidities. Chemical resistance, low water absorption, optical clarity, and dimensional stability are other outstanding qualities. At the present time it is the most available and lowest priced of the molding materials, owing mainly to the enormous monomer capacity built during the Second World War for synthetic-rubber production. It is commercially available in compression and injection molding compounds, extruded shapes such as rods from fibers to 6-in.-diameter slugs, sheets from 1/1,000 in. thickness to several inches, and tubing from small coaxial sizes to 5-in. diameters. In sunlight styrene tends to yellow slightly. Its machinability is not good. Its water absorption is so infinitesimal that its insulating qualities are not affected. Surface hardness, permanence of dimensions, and excellent mechanical properties are other outstanding characteristics. For short periods acetone has no visible effect, but for longer contacts the styrene will soften and swell. If acetone is to be used around this material, it would be better to check the results. Any percentage of aromatic hydrocarbons will cause crazing, no matter how small that percentage may seem to be. There is no dropping off of impact strength when parts molded of styrene are placed in contact with dry ice.

Chemical Resistance. Styrene molding compounds have good resistance to acids, alkalies, and salts.

They are soluble in aromatic and chlorinated hydrocarbons, esters, some ethers, and some terpenes.

They are softened or attacked by higher alcohols, gasoline, ether alcohols, ketones, glacial acetic acid, strong oxidizing acids, chlorine and bromine water, some unsaturated hydrocarbons, and essential oils.

They are resistant to lower alcohols (methyl, ethyl, propyl), mineral oils, vegetable oils, glycols, and water.

Mixtures of two or more chemicals may affect styrenes differently than would one of them alone. Action is hastened by increase in temperature, retarded by decrease. Specifically, these compounds are soluble in styrene, benzene, toluene, aromatic and chlorinated hydrocarbons, ethyl benzene, ethyl acetate, turpentine, dioxane, gasoline, ethylene chloride, cellosolve acetate, carbon tetrachloride, paradichlorbenzene, and amyl acetate.

They are unaffected by acetic acid, formic acid, butanol, octyl alcohol, salt water, most fats, sodium hydroxide (30 per cent), potassium hydroxide (30 per cent), ethylene diamine, writing inks, bleaching solutions, photographic chemicals, animal and vegetable oils and most lubricating oils, strong or weak acids, and strong or weak alkalies.

Styrene Variations. Styrene seems to lend itself to more internal variations than any of the other plastics. Chemists have brought out many combinations in the last few years that may have quite an impact on the market in the not-far-distant future. The material has such basically good qualities that it appears to be an excellent starting point for hybrids. A few of these are briefly described below.

Modified Polystyrene. Addition of chlorinated diphenyl materials to polystyrene results in a compound with nearly equivalent electrical properties with about a 10° higher operating temperature. It is noninflammable and has excellent machining characteristics.

Polydichlorstyrene. The heat-distortion point is raised to 230°F without raising the high-frequencies electric-power losses above those of regular styrene. It is transparent with a slightly yellow color. Water absorption is lower than polystyrene. High cost restricts its use at the present time. The outstanding qualities of polydichlorstyrene are therefore high temperature resistance, surface hardness, dimensional stability at high temperatures, and low water absorption.

Cross-linked Styrene Copolymers. These materials are of a thermosetting nature, and although they have distortion temperatures ranging from 217 to 235°F, they will withstand temperatures over 300° for short periods of time without ill effects. Available forms are limited to cast rods and sheets, from which parts can be machined to close tolerances. These materials are priced somewhat higher than regular polystyrenes but considerably lower than polydichlorstyrenes.

Styrene Elastomers. Styrene elastomers are a group of flexible, rubberlike styrene elastomer resins (trade name Styralloy) developed during the Second World War for cable sheathing for low-power high-frequency losses yet having good durability and flexibility under wide temperature ranges. They are flexible in thin sections and fairly rigid in thick sections. Power losses are higher than other styrenes yet are low enough to be classified with them. They have excellent abrasion resistance and remain strong and flexible during long exposures to temperatures from −90 to +212°F.

Other properties are excellent resistance to corona attack at the reduced pressures of high altitudes, stableness to oxygen and ozone, and ease of fabrication. They are usually dark-blue–gray colored and are available in production quantities in the low-cost range.

Methyl-methacrylate Resins. Publicity given to the commercial production of acrylic resins such as Plexiglas and Lucite is but the climax to a long history of chemical research. These resins, to the chemist, are polymers of the acrylic acid derivatives; to the layman they are beautifully transparent, water-white, optically perfect rods, sheets, and molded parts.

Methyl methacrylate is a thermoplastic, and the fabricator handles it in quite the same way as cellulose acetate. It is somewhat more troublesome, not only because so much is expected of it in the way of crystal clarity but because it hardens more slowly and therefore takes a longer cycle. In time there will be colors to rival cast phenolic resins. It is somewhat more expensive than cellulose acetate.

Dimensional changes in the nature of 0.002 to 0.005 in. per lin in. for at least 30 days after molding must be expected. The rate of change tapers off after that and probably disappears in 60 days. Cast forms are very stable; they are completely polymerized and have no plasticizer to evaporate.

Chemical Resistance. Active solvents for the methyl methacrylate compounds are acetone, butyl acetate, dioxane, ethyl acetate, and methyl acetate.

Slow solvents for these compounds are methyl cellosolve, benzene, toluene, carbon tetrachloride, diethyl phthalate, ketone, aromatic hydrocarbons, ether, and chloroform.

These compounds are attacked by alcohol—95 per cent—and pure methanol.

Under ordinary service conditions these compounds are not attacked by dilute alcohol, alcoholic beverages, gasoline, heptane, kerosene, mineral oils, water, vegetable oils, fatty oils, fruit acids, dry-cleaner solvent, hexane, pentane, aqueous solutions of neutral salts, dilute aqueous solutions of alkalies, hydrochloric acid, and 50 per cent aqueous sulfuric acid.

In general, the methyl methacrylate compounds are resistant to esters, ketones, alkalies, alcohols, commercial solvents, and weak acids. They are not resistant to phenol, formic acid, or mineral acids.

Polyamides. Polyamides are the well-known nylons. A whole family of these interesting plastics exists, including materials suitable for extruding into filaments, molding powders, and some resins for coatings. The greatest volume of the material now being produced goes into the textile filaments, but the molding powders are showing a steady gain. Extruded tubes and filaments for purposes other than textiles are also important industrially.

The nylon filament was the first synthetic competitor of silk that closely resembled silk chemically. It best earned the designation "artificial silk," so generally bestowed upon the rayons and their successors. Nylon is produced by the reaction of polybasic organic acids (usually dibasic) and polyfunctional amines (usually diamines), so controlled that long-chain polymers predominate. As much as possible, cross linkages are avoided. A variety of resins can be produced by varying the acid or amine used, or the proportions of each, or the conditions of polymerization. The result is a chemical compound in many ways similar to the natural proteins in its composition. It is slow burning, very tough, with good tensile strength, takes colors with difficulty, tends to absorb moisture to a limited degree, and has rather poor electrical properties. In molded form it has fair dimensional stability but somewhat lower tensile strength than in filaments. It is still rather expensive. Aside from its use as a textile material, the filament goes into bristles for brushes, surgical sutures, woven screens, cordage, etc. Molded or extruded nylon serves as gaskets, automobile-wire insulation, nonbreakable tableware, slide fasteners, combs, etc.

Polyethylene. Polyethylene was first developed in England and firstused both in England and the United States as dielectric material for flexible coaxial cables. Its power factor and dielectric constant remain nearly constant over almost the complete electrical range. Its volume and surface resistivity, arc resistance, and dielectric-strength properties are excellent.

In appearance, polyethylene is milky white, translucent, and waxlike. It has good flexibility in thin sheets, while in thick sections it is quite stiff and rigid. Its distortion temperature under 66 psi load is 122°F, its softening range between 220 and 240°F, and it has been successfully used under low loads at temperatures considerably above 122°. Standard water-absorption figures are between 0 and 0.01 per cent for 24-hr immersion. This material resists the action of all acids, alkalies, inorganic chemicals, and has no known solvents at room temperature. Three months' immersion will only produce slight swelling by such active solvents as ethyl acetate, methyl isobutyl ketone, carbon tetrachloride, and trichlorobenzene. At temperatures above 60°C, it will dissolve in a number of common solvents. Polyethylene is commercially available in a wide variety of forms and is low priced. Its outstanding qualities are chemical resistance, low water absorption, low-temperature qualities, low specific gravity.

There are no trade names for polyethylene, but it is also known as polythene. It is produced by Union Carbide and Du Pont.

Vinylidene Chloride. Vinylidene chloride resins are odorless, tasteless, and nontoxic. When molded under proper conditions, they produce articles of great strength, abrasion resistance, strong welds, dimensional stability, toughness, and durability. The material is especially suited for the injection at high speed of parts with heavy cross section. Molded products can be readily machined, drilled, sawed, and buffed.

Fittings and parts molded of vinylidene chloride resins are particularly valuable in industries involving the use of chemicals. Pipes of this material, for instance, are superior to iron pipes for disposal of waste acids in phenolic plants. Extruded tubing fitted with injection-molded flare-type fittings of the same resin makes possible all-plastic systems of like chemical resistance which are relatively leakproof because of similar thermal-expansion characteristics. Another valuable property of the tubing is its ability to withstand pressure at low temperature. Films produced from vinylidene chloride resins exhibit an extremely low water-vapor-transmission rate, flexibility over a wide range of temperatures, and heat sealability. They are particularly suitable for various types of packaging, including food products, medicinals, and metal parts.

One year of exposure at room temperature has shown the specific chemical resistance to be

Excellent to 5 per cent sulfuric acid; 10, 20, and 60 per cent sulfuric acid; 10 per cent nitric acid; 10 and 35 per cent hydrochloric acid; 10 per cent and glacial acetic acid; concentrated oleic acid, ethyl alcohol; ethyl gasoline; turpentine; lubricating oil; linseed oil; bleaching solution; 10 per cent duponal; 10 per cent zinc hydrosulfite; 15 per cent calcium chloride; water; and air

Good to 10 and 50 per cent sodium hydroxide; 65 per cent nitric acid; triethanolamine; carbon tetrachloride; and 15 per cent ferrous sulfate.

Fair to 98 per cent sulfuric acid; ethyl acetate; acetone; methyl isobutyl ketone; and benzene

Poor to ethylene dichloride; diethyl ether; 0-dichlorbenzene; bromine water; and chlorine water

Unsuited to 10 and 20 per cent ammonia and diozane

NOTE: Resistance to corrosive liquids and to organic solvents decreases with increasing temperature.

There are no trade names for the vinylidene chloride plastics. They are produced only by Dow Chemical Company and are known generally as Saran.

Vinyl Polymers and Copolymers. Just beginning to achieve commercial recognition at the outbreak of the Second World War, the vinyl polymers and copolymers have grown to be the most used of all in terms of value of output. Not only is their dollar value the greatest, but their volume is two and a half times their nearest competitor.

Although the vinyls differ in composition and properties, certain general characteristics are common to nearly all these materials. Most materials based on vinyls are inherently thermoplastic and heat-sealable. Exceptions to this are the products which have been purposely compounded with thermosetting materials or cross linking agents. In general, vinyls can be plasticized to give a wide range of hardness—from thin flexible free films to rigid molded pieces. Most of the vinyls are naturally clear materials, and unlimited color range is available for most forms of the materials. They may be made opaque as well as clear.

In their elastomeric form, the vinyls generally exhibit properties which are superior to those of natural rubber in flex life, resistance to acids, alcohols, sunlight, wear, and aging. They are nontoxic, tasteless, and odorless and are suitable for use as packaging materials which come in contact with foods or drugs, as well as for decorative packaging requiring ordinary protection. Vinyl resins can be used in printing inks. They can be effectively used in coating paper, leather, wood, and in some cases plastics. Vinyl products in most forms can be printed on.

Insulating characteristics of the vinyls adapt them for extruded jacketings for wire and cable. Other applications have been phonograph records, photographic films, and various rubberlike objects such as grommets, gaskets, diaphragms, and similar items. Films and sheeting of various degrees of rigidity and coated fabrics have been used for shoes, handbags, luggage, and the like. Coatings for fabrics have been one of the fields in which vinyls have excelled. Protective clothing and foul-weather gear have proved the efficacy of vinyls along these lines. Vinyl coatings and vinyl films and sheeting have been used in hospital equipment because of their durability and their hygienic qualities.

The vinyls have a good finish which may be smooth and satiny or may simulate leather of all kinds. They may be colored to fit into modern schemes of decoration, can be handled easily in making up complicated items; will flex around corners well, and can be stitched or heat-sealed. They are for the most part waterproof, self-extinguishing, stain resistant, stable to light, and dimensionally stable. Vinyls lend themselves to almost all conventional methods of fabrication.

Polyvinyl Chloride. Polyvinyl chloride resins exhibit a high degree of resistance to concentrated acids, alkalies, and alcohols. They are nontoxic, odorless, and tasteless. Major applications are in elastomeric forms, or in coatings. Trade names for these resins are Geon, Vinylite, Chemaco, Tygon, and Marvinol.

Polyvinyl Acetate. Polyvinyl acetate is an odorless, tasteless, nontoxic, slow-burning, lightweight, colorless thermoplastic which has reasonably low water absorption. The material is soluble in organic ketones, esters, chlorinated hydrocarbons, aromatic hydrocarbons, and alcohols. It is insoluble in water, aliphatic hydrocarbons, fats, and waxes. Water emulsions have extended the use of this resin. They are used extensively as adhesives for bonding cloth, paper, porcelain, metal, mica, wood, glass, and plastic sheets and films. Other applications for the resins include coatings for paper, sizing for textiles, and finishes for leathers; bases for inks and lacquers; stiffening agents; heat-sealing films; and photoflash-bulb linings. Trade names are Elvacet, Vinylite, Gelva, and Vinyseal.

Polyvinyl Chloride-acetate. The copolymerization of vinyl chloride and vinyl acetate forms resins of marked versatility, combining the best characteristics of both as to physical and chemical properties and general processability. They show extreme chemical inertness, being unaffected by alkalies, oxidizing agents, and most inorganic acids; excellent resistance to water; and good dielectric properties.

Rigid sheeting may be produced in all colors, transparent, translucent, or opaque. Because these sheets do not warp or shrink, they are suitable as watch crystals, drawing instruments, slide rules and other calculating instruments, instrument dials, and aircraft windows. Problems in the printing industry have been eased by the use of molded sheeting in the production of electrotypes. The high-fidelity nonfrangible transcription record successfully established in radio studios is molded of vinyl acetate-chloride. Electrical insulation, hose and tubing for beverages or chemicals, weather stripping, and channels are produced by extrusion.

Extruded monofilament is suitable for weaving fabrics of great chemical resistance and durability. Textiles woven from these resins resist shrinkages due to water. Upholstery fabrics, fireproof curtain material, cloth for raincoats, shoes and textile-printing screens are produced from these fibers. Trade names are Vinylite, Chemaco, and Tygon.

The copolymers of vinyl chloride and vinyl acetate have excellent resistance to weak acids, strong mineral acids, weak and strong alkalies, alcohols, aliphatic hydrocarbons, and mineral, animal, and vegetable oils. They swell in aromatic hydrocarbons and dissolve in ketones and esters. They are marketed under the trade names Tygon and Vinylite.

Polyvinyl Alcohol. Major applications of polyvinyl alcohol resins are in elastomeric products, adhesives, films, and finishes. Extruded hose and tubing are excellent for use when subjected to contact with oils and other chemicals. It is used as a size in the manufacture of nylon hosiery. Trade names are Elvanol and Resistoflex Compars.

Polyvinyl Formal. These resins are soluble in chlorinated hydrocarbons, dioxan, acetic acid, and mixtures of polar and nonpolar solvents but are insoluble in alcohol, acetone, benzene, toluene, and the like. Although major applications are in the field of lacquers, coatings, and impregnations, they are also employed as mold compounds. Trade names are Formvar and Formex Magnet Wire.

Polyvinyl Acetal. These resins are soluble in lacquer solvents and aromatic hydrocarbons but insoluble in aliphatic hydrocarbons. They are most suitable for application in lacquers, adhesives, coatings and impregnations, and as films. In molded form, however, they are available in sheets, rods, and tubes.

Polyvinyl Butyral. These resins are soluble in esters, ketones, alcohols, chlorinated hydrocarbons; insoluble in aliphatic hydrocarbons; and stable in dilute alkalies; but they slowly decompose in dilute acids. They are widely used as safety-glass interlayers and between sheets of methyl methacrylate to protect enclosures of pressurized cabins of airplanes against shattering. They are also used as coatings for textiles and paper and as adhesives. Trade names are Butacite, Butvar, Monsanto Polyvinyl Butyral, Saflex, Vinylite, and Horco X.

Vinyl-chloride–Vinylidene-chloride Copolymers. These copolymers were developed to furnish resins combining the unusual stability and chemical resistance of polyvinyl chloride with the solubility and plasticity essential to certain processing operations, particularly in the field of coatings. Flexible tubing of all kinds has proved successful when based on these resins. They are practical for use in wire insulation. Molding compounds find outlet in such articles as piston cups and seals for grease guns, buckets and ladles for chemicals, storage-battery jars and cases, grommets, valve disks and bellows. Calendared and cast films are suitable for protective clothing, containers, shoe soling, electrical tape, and similar items. Trade names are Geon and Glioflex.

Cellulose Acetates—Molded. Cellulose acetate is made by treating especially purified cotton linters with acetic acid and acetic anhydride. Cellulose acetate molding composition is cellulose acetate with suitable plasticizer, pigments, and dyes. It is thermoplastic, changing its form under the application of heat and pressure without any chemical change (known as curing). It is generally necessary to cool the mold about 100°F below the molding temperature before removing the casting.

Advantages. The chief advantages of cellulose acetate molding composition over other molding compositions are extreme toughness, resilience, and high polish. Because of its toughness it can be used in thin-walled sections where other molding compounds are inadequate because of their brittleness. It is particularly adapted to the molding of articles which come in contact with the skin since it is a low conductor of heat, takes an exceptionally smooth finish, and is pleasant to the touch. It is also without odor or taste.

Colors. Colors available are colored and crystal transparent, slightly pigmented but unfilled translucent, and variegated configurations of mixed-color mottles. The price range on the raw material is wide depending on the brilliance of the color required. Pearl effects are available but rank among the most expensive. Any color can be matched, but a guaranteed minimum of 200 lb for each color is required to hold the standard price. Five thousand pounds of a group of colors rates the minimum price on raw material.

Water Absorption. Cellulose acetate owing to its average 1.9 per cent water absorption, is not suitable for use as containers for water or anything containing water.

Heat. Because it is thermoplastic, softening at 150°F, and not in any way changing its chemical composition as phenolics and ureas change, this material should be used only at temperatures below this figure. Cellulose acetate differs from cellulose nitrate in its reaction under extreme heat. It merely burns like heavy cardboard, fiber, or wood. It is listed under the Underwriters' Laboratories Re-examination Service and rated as follows: "Hazards of this product in use are judged to be small and in storage somewhat less than would be presented by common newsprint paper in the same form and quantity."

Workability. Cellulose acetate has excellent machining qualities, using standard brass-working methods. Two-flute tools are better than those with three or four since they clear the material away faster. The material has an abrasive action which tends to dull the tools; therefore the tools should be nitrided. The basic action of machining should be confined to cutting rather than filing or sanding. It should be cut, turned, punched, or scraped rather than filed, sanded, or burred. Do not overheat.

Cementing. The two surfaces to be joined should be as smooth as possible and absolutely clean. Rough surfaces or a film of oil will cause a poor bond. Lightly pigmented compounds can be cemented by melting the contacting surfaces with acetone. More heavily pigmented compounds do not take the bond so easily. Properly done, an excellent bond can be obtained. The raw-material manufacturers have special cements, one of which may be found necessary.

Chemical. Cellulose acetate is uninjured by contact with vegetable and most mineral oils. Alcohols and some essential oils of an aromatic nature are partial solvents and will soften or spot the surface of a molded piece. Dilute acids and alkalies have only a slight effect, but the material decomposes under increasing concentrations. The passage of time and the action of sunlight have very little effect. Cellulose acetate is soluble in ketones and esters such as acetone, ethyl acetate, cellosolve; softened by alcohol; insoluble in hydrocarbons like benzine, toluene carbon tetrachloride, oils (see Table 34-1).

NOTE: Articles coated with pyroxylin or cellulose nitrate lacquer should not be placed in direct contact with parts molded of acetate powder. The plasticizers in the acetate soften the nitrate film causing tackiness which may result in a portion of the film being removed when the two articles are separated.

Each manufacturer of cellulose acetate molding compound has several formulas which he supplies the molder to fit certain conditions. For instance, the molders can buy a compound with emphasis on free flow, fast setting, welding, optical, and the like. These formulas are based on different plasticizers. In each formula the physical-flow properties of the material can be again varied by the percentage of the plasticizer used. These flow variations range from H_7—a very low percentage of plasticizer, hence a very reluctant flow—down through H, MH, M (for medium), S for soft, and a range of S numbers, even to S_{10}. Some formulas have as many as 14 different flows available, none fewer than 7.

An all-purpose formulation may range from H_2 to S_6 in 11 steps. The molded parts are very different in physical properties, while electrical properties are not affected appreciably.

Table 34-1. Chemical Effects of Cellulose Acetate Molding Compound

	Reagent	Effect
Acid, standard	30 % sulfuric	Partially decomposes
	3 % sulfuric	No change
Supplementary	10 % nitric	Decomposed
	5 % acetic	No change
	10 % hydrochloric	Decomposed
	Oleic	No change
Alkalies, standard	10 % sodium hydroxide	Decomposed
	1 % sodium hydroxide	Much softened and swollen
Supplementary	10 % ammonium hydroxide	Decomposed
	2 % sodium carbonate	No change
Solvents, standard	95 % ethyl alcohol	Softened, blushed, swollen
	50 % ethyl alcohol	Softened, blushed, swollen
	Acetone	Dissolved
	Ethyl acetate (85–88 %)	Dissolved
	Ethylene dichloride	Dissolved or very soft—flabby
	Carbon tetrachloride C.P.	No change or swollen
	Toluene	No change or swollen
	Gasoline (white)	No change
Miscellaneous, standard	Water	No change
	10 % sodium chloride	No change
Supplementary	3 % hydrogen peroxide	No change

Cellulose acetate molding compounds are made under the following trade names: Ampacet, Fibestos, Koppers, Lumarith, Nixon C.A., Plastocele, and Tenite I.

High-acetyl Acetate. In ordinary cellulose acetate the percentage of the combined acetic acid runs from 5 to 56. From 56 to about 62, the product is called high-acetyl acetate. This material has come into its own mainly during and since the Second World War. It requires special solvents to make it and is more tricky to mold. Moisture and heat resistance are improved over the regular type of acetate, also resistance to organic solvents, to mineral, animal, and vegetable oils, and to gasoline. It loses none of the inherent qualities of toughness, strength, and resiliency for which cellulose derivatives are noted.

Effects of sunlight and outdoor aging are dependent upon the locality in which the articles are exposed and their particular composition, *i.e.*, the type and quantity of plasticizer, etc. Requirements for resistance to outdoor exposure should be considered a special problem. Experience has shown that articles molded from cellulose acetate remain fully serviceable with indoor aging at normal temperatures.

Cellulose Acetate Butyrate. Cellulose acetate butyrate molding compositions are made of cellulose acetate butyrate and plasticizers with or without the addition of pigments or coloring matter. Cellulose acetate butyrate is made by the esterification of alpha-cellulose with acetic and butyric acids and anhydrides in the presence of a catalyst. For chemical effects, see Table 34-2.

Table 34-2. Chemical Effects of Cellulose Acetate Butyrate

	Reagent	Effect
Acid, standard	30 % sulfuric	No change
	3 % sulfuric	No change
Supplementary	10 % nitric	Discolored
	5 % acetic	No change
	10 % hydrochloric	No change
	Oleic	No change
Alkalies, standard	10 % sodium hydroxide	Slightly softened
	1 % sodium hydroxide	No change
Supplementary	10 % ammonium hydroxide	Discolored
	2 % sodium carbonate	No change
Solvents, standard	95 % ethyl alcohol	Swollen
	50 % ethyl alcohol	Swollen
	Acetone	Dissolved
	Ethyl acetete (85–88 %)	Dissolved
	Ethylene dichloride	Dissolved
	Carbon tetrachloride C.P.	Much swollen
	Toluene	Much swollen
	Gasoline (white)	No change
Miscellaneous, standard	Water	No change
	10 % sodium chloride	No change
Supplementary	3 % hydrogen peroxide	No change

Their stability is good under service conditions because they show very little loss in weight over long periods of time because of the fact that the plasticizers used have low volatility, low solubility in water, and are present in relatively small quantities. Because of the low plasticizer content, moldings have an excellent finish and usually do not require buffing. Certain hard formulas will resist distortion and impairment when boiled for a short period of time. Other outstanding properties are their toughness, high impact strength, wide compatibility with organic substances, and their ease of molding. Choice of this material should be governed by whether average properties are sufficient for the intended purpose or whether superior resistance to either heat or impact may be required. It should be remembered that, in general, superior shock resistance is obtained at a sacrifice of heat resistance and conversely.

Cellulose acetate butyrate compounds are used for such items as toothbrushes, telephones, toilet float bulbs, bayonet scabbards, pistol grips, gas-mask valves and guards, and steering wheels.

Effects of sunlight and outdoor aging are dependent upon the locality in which the articles are exposed and their particular composition, *i.e.*, type and quantity of plasticizer, etc. Requirements for resistance to outdoor exposure should be considered a special problem. Experience has shown articles molded from cellulose acetate butyrate remain fully serviceable with indoor aging at normal temperature.

Cellulose Propionate. Cellulose propionate, was the first new plastic to be announced after the close of the Second World War. Too little experience is available at this moment to do more than cite the claims of its makers, the Celanese Corporation of America. They state it has the best balance of basic characteristics of any cellulose plastic in existence today.

Its dimensional stability, impact strength, beauty, and moldability are said to be outstanding. Chemically it is a straight cellulose ester, cellulose propionate combined with suitable plasticizers. The propionate is made in the form of a flake by the reaction of propionic acid and anhydride with wood pulp or cotton linters in the presence of a catalyst. Propionic acid is a 3-carbon acid falling between acetic and butyric in the fatty-acid series. The propionic acid for this new plastic comes from petroleum raw materials.

Specific gravity is 1.2. Impact strength is roughly twice that of cellulose acetate. Moisture absorption is low, expansion in high humidity a minimum. Dielectric strength is the same as cellulose acetate; power factor and dielectric constant are lower. The trade name for cellulose propionate is Forticel.

Ethyl Cellulose. Ethyl cellulose plastics are made from the ethyl ether of cellulose combined with suitable plasticizers, mold lubricants, and coloring agents. They are distinct chemically from the other cellulose plastics, which are esters of cellulose. The well-known chemical stability of ether compounds is reflected in their stability to hydrolysis, or to chemical breakdown, and to their resistance to dilute acids, to concentrated and dilute alkalies, and to heat. Moldings of these thermoplastic materials are outstanding in toughness and strength, low temperature, shock resistance, and retention of original properties on aging or on exposure to a wide range of temperature-humidity conditions. Their moldings also possess excellent dimensional stability and a high degree of resistance to water and distortion by heat. They are free from odor, light in weight, and have good insulating qualities.

Cellulose Nitrate. Cellulose nitrate is the oldest of the group of plastics now in common use. It is not moldable because of its flammability, a disadvantage that has been the subject of much expensive research by its makers without too much in the way of results. Parts made of nitrate are formed or machined. It is the toughest of all the thermoplastics. This quality and the ease of fabrication are its chief advantages. Other desirable qualities are its dimensional stability, resilience, low water absorption, and resistance to mold acids. A wide variety of transparent, opaque, and mottled colors can be produced. It may be cut, sawed, punched, drilled, drawn, embossed, printed, polished, and swaged. It is easily cemented to itself and other materials.

It is widely used in fountain pens, spectacle frames, and drawing instruments, where dimensional stability is necessary.

It is available in beads, color chips, lacquers and emulsions, rods, tubes, and sheets of various thicknesses, usually 20 by 50 ft standard.

Benzyl Cellulose. Among the most noteworthy properties of this new material, benzyl cellulose, are its extremely low moisture absorption, 0.44 per cent in 24 hr, its excellent electrical properties, including high arc resistance, and its good resistance, when properly formulated, to chemical attack. It may have a definite place in the plastics field as a hot-melt coating, extruded on wire for electrical insulation, or in extruded or injection molded shapes. Its trade name is Hercules Benzyl Cellulose.

Methyl Cellulose. Methyl cellulose is forming a long-felt need in industry for a powerful synthetic thickener, free from property variations present in natural gums because of their variable growing conditions.

It is used in the field of emulsions, particularly in water-emulsion paints. In the packaging industry, the property of oil and grease resistance makes it very useful. Its trade name is Methocel.

Polyisobutylene. Polyisobutylene first appeared in Germany under the name of Oppanol and was later introduced in the United States as Vistanex.

It is made in a wide range of molecular weights which produce materials from lubricants to tough rubberlike polymers.

It is not used alone because it undergoes considerable cold flow and has little structural strength. It is compatible with a wide variety of other materials and is used to change and improve their qualities. It can also be compounded with various fillers. It differs from natural rubber in that it cannot be vulcanized. It is completely saturated and therefore has good resistance to strong chemicals and ozone. It is used in cable insulation and sheathing and is available in commercial quantities at low prices.

Polytetrafluorethylene. This material known as "Teflon," is a remarkable resin that possesses mechanical toughness over a wide range of temperatures and excellent electrical properties over a wide band of frequencies. Teflon is chemically inert and has high heat resistance. It has no true melting point. At about 420°F small amounts of gas are given off, and at 750°F it decomposes slowly. While its heat-distortion temperature is 266°F, it can be used over a temperature range of 100 to 480°F. Dielectric losses of Teflon are practically constant from 60 cycles to 3,000 megacycles and are as low as either polystyrene or polyethylene. Its resistance to surface arcover is high, and on failing it melts and vaporizes and does not leave a carbonized conducting path. Boiled in aqua regia, hydrofluoric acid, or fumic nitric acid, it shows no change in weight or properties. The effect of strong alkalies and organic materials is almost zero, and outdoor weathering gives no detectable change in a 1-year test. It can be extruded as rods and tubes or as a wire coating. Compression molding of simple articles can be done, but more complicated shapes must be machined.

Teflon can be machined easily with regular wood- or metal-working tools if they are kept sharp. So far no usable cements have been found. Only limited quantities are available.

Casein. Casein has been known for a long period as milk curds or cheese, which is casein in a very impure form. It occurs in the milk of all mammals, although it differs in quality and quantity from one species to another. An average cow's milk carries in suspended or colloidal condition about 3 per cent of this material, which is best described as phosphoprotein, a line compound in combination with calcium phosphate. A perfectly clean and, so far as possible, neutral separated milk is used, and a quantity of rennet is added. Rennet casein is usually chosen as being most suitable, giving the toughest finished raw material.

If casein is to be made into sheets, the extruded material is placed in hydraulic presses, compressed to the desired thickness, cured in formaldehyde, dried, and straightened. If the material is to be used as rods, the extruded rods are cured, dried, and ground to size.

It is made and sold in the form of sheets, rods, and tubes. Ameroid and Galom are trade names for casein.

Lignin-base Compounds. Lignin is nature's binder in the formation of growing things. It is widely used in forming wallboard and sheets of various sorts but has not proved itself in competition with phenolics for individual shaped pieces. Its principal attraction is its low price, but this is overborne by the need to chill in the mold and its reluctant flowing qualities. Woody materials consist of water solubles, such as turpentine, rosin, tannin, and the like; wood-sugar anhydrides, which can be converted by acid hydrolysis to water solubles; cellulose, the fibrous portion; and lignin, the binder. In papermaking the lignin is removed. In the process of making lignin-base materials, the chips of wood are heated under high pressure which is suddenly released, resulting in an explosion of the fibrous material. The mass is treated to remove the sugars, and a moldable material is left. The lignin pulp remaining is essentially a thermoplastic material but definitely does not lend itself to injection molding. As a compression-molding compound it reacts with amines, furfural, and phenol to form a thermosetting resin. An average formula would be 15 to 28 per cent phenol resin and 77 per cent ground-lignin pulp. It can be pulled hot from the mold.

Shellac. In the plastic-molding field the first extensively used material was porcelain. While this material had excellent heat-, water-, and electrical-resistant properties, its brittleness and lack of accuracy led to the development of rubber binders. These in turn were displaced by the use of shellac compounds because of the constantly increasing price of rubber. Shellac as a binder in a molding compound probably outdates any other binder known. Other natural gums such as copal, sandroc, etc., have been incorporated in the mixtures as the price of shellac rose. The fillers used are innumerable, but the outstanding ones are asbestos, mica, marble flour, and wood flour.

The applications of shellac materials are varied and widely diversified. Finish is excellent, the parts taking a high polish. Accuracy can be maintained within 0.002 in. if necessary. Dies are about the same as used for phenolic materials. For a long period shellac products were marketed in practically any color, but now only natural and black are used.

The material is rather brittle. It is noncombustible and will not sustain flame. It has a good weather resistance and is practically impervious to moisture. Its greatest disadvantage is its low heat resistance which at present has a limit of 175 to 180°F.

Various experiments are under way to raise this softening point. These may, if successful, increase the popularity and application of this material. A trade name for shellac is Complac.

Cold-molded Compounds. Cold-molded compounds can be grouped in three classes: those using bitumen binders, cement binders, and resin binders. The most widely used are the bitumen binders consisting of asphalt or gilsonite, drying oils, drier, coloring matter, and occasionally a small percentage of natural gums combined with asbestos fiber, the latter about 80 per cent of the resulting compound. Impact and tensile strength are about half those of phenolic materials. Cost of material and dies is considerably less than for hot-molded phenolics. When strength is required and weight and volume are not important, cross sections can be increased considerably and costs still kept low.

In brief, the three types can be characterized as follows:

Bitumen binders are the least expensive and are used principally in parts requiring a high degree of plastic flow in molding.

Cement binders have great physical strength and high heat and arc resistance when suitably treated. Their cost relatively high.

Resin binders are physically stronger but not so heat resisting as bitumen binders.

PLASTICS VERSUS METALS

Any attempt to compare plastics and metals on a competitive basis is difficult because of the versatility of both groups of materials. The general idea that plastics will in some way be competitors of metals (especially light metal) may be true to a certain extent, but the area of overlapping will be found to be comparatively small. Plastics are not a tonnage industry as are practically all metals. Even magnesium, the newest metal, is being produced at something like double the entire output of plastics. Even in the competitive area the rivalry is not general. *Molded plastics* compete with metal chiefly when metals are die-cast, sand-cast, or machined. *Laminated plastics* are competitors of metals when the latter are considered in sheets, formed, or machined.

Resin coatings compete with metals used as plating mediums. These are the three principal occupants of the zone where plastics and metals overlap. Outside this area the two types of materials are "mutually exclusive." Plastics cannot be used where continuous heat above 400°F will be applied. Plastics lack the surface hardness of most metals, although many plastics seem to be better under abrasion than many metals. Again, if only a small space is available and the cross section therefore limited, metals are invariably chosen because they provide the requisite strength.

Broad Distinctions. Plastics are beyond the competitive reach of metals where (1) satisfactory electrical insulating quality is required; (2) a material is needed that will waterproof textiles so as to leave them flexible enough to use as raincoats, shower curtains, and the like; (3) transparency is required; (4) a material is sought that is suitable for protection against ordinary heat conduction in such simple applications as coffee-pot, gas-stove and electric-iron handles, and numerous other similar parts; (5) the material must feel warm and comfortable to the touch; and (6) a choice of built-in colors is desired. If those were the sole bases of comparison between plastics and metals, metals would already be at the start of a long decline. However, the problem cannot be settled so simply in favor of either side. In the two most important fields where the choice may be difficult—formed metals vs. molded plastics and sheet metals vs. sheet plastics—it may be necessary to draw finer distinctions. Not all metals can be formed with equal ease. As with plastics, compromise is usually invoked. A certain alloy steel may be ideal as to service quality, but to form it into the shape needed may involve prohibitive cost. Molded plastics need rather expensive steel molds, but so do metal die castings. Sand-cast metals offer a cheaper approach but may leave too much machining to be done to obtain the needed accuracy. Plastics molded parts seem to fit into a middle band of accuracy. If the part is really rough and $\frac{1}{16}$ in. means nothing, a sand casting is indicated; if the tolerances, however, are less than 0.001 in., carefully machined metal is a better choice. Between these two, molded plastics may be considered. Other things being equal, the greatest advantages plastics offer are built-in colors and surface permanence. Plastics are not affected by either corrosion or electrolysis. Die-cast or stamped metal is preferable when thin sections must be rigid or bear any appreciable strain. Strong thin plastic parts can easily be made in limited shapes by using reinforcements of laminates or fiber stocks, but they will not be rigid. Plastics can be threaded as well as metals if there is enough "stock" around the thread to prevent its cracking out.

Table 34-3. Comparison by Weight of Some Plastics and Metals

(Lightest at top of the list)

Materials and characteristics	*Specific gravities*
Formica Pregwood No. 100; impregnated compressed wood; all laminations parallel, classed as a high-strength product, water absorption 6 per cent maximum	1.30
Formica-canvas laminate phenolic; grade C; cotton fabric—4 oz per yd; tough; water absorption 0.3 per cent	1.33
Formica-paper-base laminate-phenolic; grade X; primarily for mechanical applications; water absorption 4.0 per cent	1.33
Bakelite wood-flour phenolic BM-120—best all-round molding composition; water absorption 0.3 per cent	1.36
Bakelite macerated-canvas phenolic BM-3510; high-production, high-impact molding; water absorption 1.0 per cent	1.38
Formica-glass-mat-base phenolic; grade MF; basically for electrical purposes; water absorption 0.35 per cent	1.50
Formica asbestos-fabric-base laminate—Grade AA; strength, toughness, minimum dimensional changes; water absorption 1.5 per cent	1.80
Magnesium alloy (AM-585)	1.81
Aluminum alloy (24 ST)	2.80
Stainless steel.	7.85
Chrome-moly steel	7.85

Engineering Factors in Selection. The first factor determining the choice of plastics or metals is the available space or volume of the part. If it is relatively small, plastics are almost automatically out unless their use is demanded by one of the six "exclusives" mentioned. The second factor is cost. All plastics cost more than metals on a pound basis. The saving lies in their low specific gravities (see Table 34-3). Even magnesium with a specific gravity of 1.80 is higher than the average range of 1.06 to 1.50 for plastics. A correction of the usual strength values for the specific-gravity effect may bring plastics into the range of the engineering metals.

To make any comparison, the very best plastics material must be chosen, and one of the weaker alloys should be selected.

On this basis, tensile-strength comparisons should be made (see Table 34-4). Chrome-moly steel and stainless steel show around 180,000 psi; aluminum alloy, 62,000; and magnesium alloy, 46,000. One of the strongest plastics is Pregwood, (impregnated plywood). Its tensile strength is 30,000 psi. Other "strong" plastics are paper laminate at 12,500 psi; canvas laminate, 9,500 psi; and wood-flour-phenolic molded parts, 8,500 psi. It is evident that plastics offer no competition in direct comparisons of this type.

Table 34-4. Comparison of Strength–Weight Properties of Plastics and Metals

Material	Specific gravity	Tensile strength, psi	Modulus /sp gr	Ratio (magnesium alloy = 100)
Magnesium alloy	1.81	46,000	25,400	100
Stainless steel	7.85	185,000	23,600	93
Pregwood	1.30	30,000	23,000	90
Chrome-moly steel	7.85	180,000	22,900	90
Aluminum alloy	2.80	62,000	22,100	87
Paper laminate	1.33	12,500	9,400	36
Glass-fabric laminate	1.50	14,000	9,300	36
Canvas-fabric laminate	1.33	9,500	7,100	28
Wood-flour phenolic, molded	1.36	8,500	6,200	24
Asbestos-paper laminate	1.80	10,000	5,500	21
Impact phenolic molded	1.38	7,500	5,400	21

When determining specific tensile strength or tensile strength per pound (see Table 34-4) by dividing the strength figures by specific gravity, one of the plastics, Pregwood, moves to third place on the list at 23,000, following magnesium alloy at 25,400 and stainless steel at 23,600. Chrome-moly steel at 22,900 and aluminum alloy at 22,100 are far above paper laminate at 9,400, canvas laminate at 7,100, and wood-flour phenolic, molded, at 6,200.

This comparison shows that, if competition is confined to sheet materials, the plastics stand up fairly well in tensile strength by weight, but the moment it centers about shapable forms, by bringing in the moldable group, the plastics lose position rapidly.

With respect to compressive strength, the steels are strongest, with some of the plastics better than some of the other metals (see Table 34-5). When the specific-gravity correction is applied, all the plastics except Pregwood rate higher than the metals. Therefore, if compressive strength is the determining factor in a specific design, plastics (some form of thermosetting phenolic or urea) will serve the purpose best pound for pound.

Similar data on modulus of elasticity in tension, which is a measure of a material's rigidity, are given in Table 34-6 and show clearly that the metals are outstanding in this respect even on a per-pound basis. Plastics are very inferior to metals with regard to shear, impact, and flexural strengths.

Metal is chosen over plastic where there is a really severe application of an engineering nature, unless the stronger metal has its own disadvantage (such as poor resistance to corrosion or electrical characteristic) that may be even more serious than the mechanical deficiency of the plastic.

When compressive strength is important in design, almost any kind of thermosetting plastic material, except plywood, will give the best results on a pound basis. Under tension plywood compares favorably with leading metals on a pound-for-pound basis.

Plastics have a few outstanding service qualities where the previously mentioned measures of strength are not all-important. One of these is abrasion resistance. Ammunition chutes of laminated phenolic outwear steel. Plastic gears are not only quieter but wear as well as steel. Under impact plastic sheets will not dent and gradually deform before failure but will break suddenly, while metal, although it will not fail completely, will deform. Plastics will dampen machine chatter better than metals, resulting in less noise and vibration.

Sheets of plastic cannot be drawn to new shapes so easily as metals, but usually when odd shapes are desired they can be created in the plastic itself without making the sheet. In other words, sheets of metals are raw materials suitable for a great deal more working than sheets of plastics.

There is one unfortunate characteristic of plastics that occurs also in metals but not to such an extent, and that is creep. Creep (cold flow) is the constant change in dimension under stress. The thermoplastics are strongly subject to this and therefore are avoided for stressed service. In the thermosetting materials, creep is present, but unless the material is used with practically no factor of safety, it may be discounted.

Table 34-5. Compressive Strength Weight Values of Plastics and Metals

Material	Specific gravity	Compressive strength, psi	Modulus /sp gr	Ratio (canvas laminate = 100)
Canvas laminate	1.33	38,000	28,000	100
Paper laminate	1.33	35,000	26,000	93

PATENTS

BY SHELDON H. GRAVES

Attorney of Emery, Holcombe and Blair, Patent Attorneys, Washington, D.C.

DEFINITION

A *patent* is a grant by the Federal government to an inventor, his assigns, or personal representatives of exclusive right to make, use, and vend the subject matter of his invention for a limited time throughout the United States and the territories. The term of a patent is 17 years except for a design patent, which may be for 3½, 7, or 14 years, as the applicant for design patent may elect.

A patent may also be considered as a contract between the inventor and the public whereby, in consideration of a full disclosure of the invention to the public, which disclosure is contained in the description and drawing, if any, of the patent, the inventor is granted the exclusive right to practice the invention as this invention is defined in the claim or claims of the patent.

The patent grant is statutory under authority granted to Congress by the Constitution of the United States and differs from the common-law right of the inventor which is merely the natural right to practice his invention and to keep the invention secret until others have acquired knowledge of it. The exclusive right granted by a patent is the right to exclude others from making, using, or vending the subject matter of the invention and does not enlarge the inventor's common-law right to practice his invention.

APPLICANTS, APPLICATIONS, AND PROCEEDINGS

Applicant. An application for patent must be made by the inventor if alive and sane. If the inventor is dead, the application may be made by his executor or administrator and, if insane, by his legally appointed guardian, conservator, or representative.

An inventor is a sole inventor when he alone has conceived the invention, or he may be a joint inventor when he, with one or more others, has contributed to the conception of the invention.

An inventor may hire someone to work out the details of the invention, to embody it in practical form, or to build a model or make drawings. This, however, does not make the one so employed a joint inventor with the employer, even though the one so employed in the course of his duties makes an ancillary invention. One who furnishes capital for the development of the invention or for the filing or prosecution of a patent application thereon does not thereby become a joint inventor, and he cannot be a joint applicant with the one who has conceived the invention, although he may be a joint patentee.

Application. An application for a patent must be signed by the inventor and filed with the Commissioner of Patents in Washington, D.C., and all business with the Patent Office connected therewith is in writing and in the name of the applicant, who may and usually does employ an attorney to conduct the proceedings.

Rules for the filing and prosecution of an application, together with forms to be followed are given in the "Rules of Practice of the United States Patent Office in Patent Cases," a copy of which may be obtained for 40 cents by addressing the Commissioner of Patents. Attention will be called in the following pages to certain requisites of papers filed in the Patent Office. The mention of such requisites is not intended to be all-inclusive, and the "Rules of Practice" should be consulted in every case.

A patent application comprises a petition, signed by the applicant, addressed to the Commissioner, and requesting the grant of a patent; an oath signed by the applicant and executed before a notary public or other designated officer who must place his official seal on the instrument, which petition and oath should follow the form presented by the "Rules of Practice"; a specification and claim or claims, which must also be signed by the applicant, and a drawing when the invention is susceptible of disclosure by drawing. The drawing must be signed by the inventor or his attorney. The petition usually includes the appointment of an attorney to prosecute the application. The petition, oath, specifications and claims, and power of attorney, if one is used, may be included in a single document and may be executed by a single signature of the applicant if an approved single signature form supplied by the office or approved by the office is used.

Application papers must be accompanied by the filing fee, which at the present time is $30, plus $1 for each claim in excess of 20, except in design cases, in which the entire fee is $10, $15, and $30, for terms of 3½, 7, and 14 years, respectively.

The specification, which should follow the orderly form prescribed by the "Rules of Practice" begins with a general statement of the object and nature of the invention which may include reference to advantages of the invention over the prior art. There then follows a brief description of the drawings, if there are drawings, and a detailed description of the invention. The description as a whole must be so clear and complete that one skilled in the art to which the invention relates, on reading the same, may reproduce the invention in a concrete operative form without the necessity of his exercising any invention of his own.

Unnecessary details need not be given in the description provided they can be supplied by one skilled in the art. This is also true of the drawings. They need not show parts in exact dimensions or proportion unless such dimensions or proportions are part of the invention itself. In an application for a design patent, inasmuch as the invention resides in the appearance of the article, a description which merely refers to the drawing will be sufficient.

The drawing must conform to the requirements set forth in the "Rules of Practice." The figures of the drawing, which should be consecutively numbered, are described in the specification in the brief description of the drawing above noted, and reference characters should be applied to parts of the structure shown and such reference characters included in the description of such parts in the specification.

The description is followed by the claims. A claim is a formal statement of the invention stripped of extraneous matter and defines the patent right or monopoly sought. Where the invention is an article of manufacture or a machine, the claim recites the part or combination of parts constituting the invention and should state so much of the characteristics of the part or of the relationship of the parts of a combination that the manner in which the parts cooperate between themselves or with others is clear. Similarly, a process claim recites the step or combination of steps constituting the process, and in a claim for composition of matter the ingredient or ingredients are so set forth.

Claims quite often state the art to which the invention relates, in the form of an introductory clause; *e.g.*, "In a double-acting pump, the combination of, etc.," or "A lubricant consisting of, etc." In a design patent the claim is merely for the particular article as shown.

Claims can be classified as *generic* or *specific*. A generic claim is one which describes or "reads on" several embodiments of the invention or is limited to features which are common to a number of embodiments. A specific claim is one which reads on only one embodiment or on a fewer number of embodiments than a generic claim.

It is common practice to include in the application broad or generic claims as well as specific claims. If eventually it turns out that the invention is broadly new, both kinds of claims are valid. If some prior specific embodiment of the invention which would be included under the generic claim, but not under the specific claim, should subsequently come to light, the specific claim would still be valid.

As the drawing of claims adequate to protect the invention disclosed requires a high degree of skill and experience, the applicant, unless he is very familiar with this practice, is advised to employ a competent patent attorney.

Proceedings. When the patent application is filed in all its parts, the Patent Office gives it a serial number and informs the applicant of the number and the date of filing. The date of filing, if the application discloses an operative invention, constitutes a record date of invention and prima-facie proof of its reduction to practice and is the date upon which the Office regards the invention as having been completed in the absence of other evidence, the importance of which will be more fully discussed hereafter.

When filed, the application is sent to an examining division which examines applications in the art to which the invention relates, and in the course of time (usually several months) the first official action on the application is mailed to the applicant's attorney or to the applicant.

In this office action attention will be called to any informalities in the application papers. Note may be made of grammatical errors, and if there is anything not clear in the description, the applicant will be required to clarify the same by amendment. In many applications, for record purposes as filed, structures or modifications are described in the specification which are not shown in the drawing. In this case the examiner will require that the structure be shown in the drawing or the description of the same canceled from the specification.

If the disclosure or any part thereof is considered inoperative, the applicant's attention will be called to this fact, and he will be called upon to correct the same by amendment. In doing so, or in amending for any other purpose, care must be taken not to introduce into the application any new matter, *i.e.*, any substantive matter not predicated on the disclosure of the specification, drawings, or claims as originally filed. However, simple changes may be made where it is obvious to one skilled in the art what is needed to correct the inoperativeness. Where the inoperativeness goes to the essence of the invention and cannot be remedied without the introduction of new matter, the application is fatally defective.

Informalities in the claims will also be called to applicant's attention, and where the invention claimed can be understood, the examiner will give an action on the merits of the claims unless as a preliminary matter he requires division or requires election of species.

Division. Division is required when the examiner finds that applicant has claimed in his application two or more independent inventions. Where such is the case he will be required to elect which invention he desires to prosecute in that particular application and to limit the claims in such application accordingly. He may claim another of the disclosed inventions in a second or divisional application, which should be filed while the first application is still pending in order that such second application shall have the benefit of the filing date of the first application.

In response to a requirement for division, the applicant may file an argument to the effect that the inventions claimed are not independent and are such as may properly be included in one patent. The examiner then usually refers the question to another examiner known as the classification examiner, who will approve or disapprove the requirement for division, and on approval the examiner in charge of the application will repeat the requirement and make it final. From such final requirement, appeal may be taken to the Board of Appeals; or the applicant may elect which invention he wishes to prosecute, continue the prosecution of such invention, and later appeal to the Board of Appeals on the question of division along with such other matters as may then be appealable, should he so desire.

Election of Species. Election of species may be required when the applicant discloses more than one embodiment of the invention or more than one way in which the invention may be carried out and at the same time separately claims different specific embodiments. Where the applicant files an allowable generic claim covering more than one embodiment of the invention, he may claim specifically in separate claims different embodiments of the invention, not exceeding three, provided all three fall under such generic claims. When there is no such allowable generic claim, the applicant will be required to elect which species he desires to prosecute, and thereafter claims to such species only will be considered on their merits.

Whenever a requirement for division or for election is to be made, the examiner usually makes a cursory examination of prior art and in his requirement cites such patents or publications as may assist the applicant in making his election.

When such preliminary questions as above noted are disposed of, the action on the application will be directed to the merits. The claims will be acted on individually, and they will be allowed or rejected. When rejected, the reasons for rejection will be fully given, and where patents or publications are cited in rejection, sufficient information will be furnished applicant to enable him to order from the Patent Office copies of such citations.

The applicant is given 6 months in which to reply to an office action unless for some special reason the examiner specifies a shorter period. The applicant's reply should be completely responsive. Whenever the applicant considers that an objection or rejection of the Examiner is not proper, an argument should be filed giving the reason why it is thought the position taken by the examiner is not proper. Otherwise, the applicant should amend the specification, claims, or drawings, as the case may be, to avoid the objection or rejection.

Amendment to the specification is made by directing specifically that certain matter be canceled or changed or that certain matter be added. The claims may be amended in the same manner, or original claims may be canceled and others substituted or other claims added to those originally filed. Amendments to the drawing usually take the form of a letter requesting the chief draftsman of the Patent Office to make the changes desired, which letter is accompanied by a sketch showing the changes to be made. The Patent Office makes a reasonable charge for such amendments and may demand a deposit to cover such charges.

In applicant's response to an office action he should reply to every point raised by the examiner. Correction of mere informalities will generally not be insisted upon until the application is deemed to contain allowable or patentable subject matter or the application is in condition for appeal.

When the applicant has replied to an office action, the office will again act on the application. Further objections may be raised and new references cited and new reasons for rejection given. The applicant always has a right to reply or amend as long as new references or new reasons are cited for refusing a patent.

When the examiner rejects on the same references and for the same reasons as have been previously given, he can and generally does make the rejection final. At this stage of the case the applicant presumably has presented his reasons for believing the claims patentable, the examiner still believes them unpatentable, and, an issue having been reached, if the applicant wishes to proceed further, he should appeal to the Board of Appeals.

When such an appeal is taken, the examiner forwards to the Board of Appeals a statement giving the reasons for rejection and sends a copy to the applicant. The Board of Appeals then sets the case for hearing and appellant is required within 60 days from the date of appeal or within 6 months from the date of the action appealed from, to file a brief, which complies with provisions set forth in the "Rule of Practice," at the same time indicating if he desires an oral hearing. If so, the applicant may appear at the hearing and orally argue his case.

From a decision of the Board of Appeals of the Patent Office affirming the rejection of the examiner appeal may be taken to the United States Court of Customs and Patent Appeals; or, alternatively, a bill in equity may be brought against the Commissioner of Patents in the United States District Court for the District of Columbia.

Abandonment of Application. Where no proper reply is made to any office action within 6 months or such shorter time as may be fixed, the application is held abandoned. Unless such an abandoned application can be revived, it is to all intents and purposes dead. A new application can be filed for the same subject matter, but it cannot relate back to the filing date of the abandoned application for the purpose of establishing a date of completion of the invention.

In order to revive an abandoned application, it must be shown to the satisfaction of the Commissioner of Patents that the delay in prosecuting the same was unavoidable. A petition to the Commissioner to revive the application is filed accompanied by a verified statement of facts showing that the delay was unavoidable. Any explanation for the cause of delay should cover the entire period of delay up to the time of filing the petition to revive.

Related Application. Divisional applications have previously been mentioned. They are applications wherein the subject matter or disclosure has been carved out of an earlier filed copending application.

Another type of application commonly met with is called a continuation in part. It often happens that an inventor, after having filed an application on a particular invention, conceives of some improvement or modification which includes more or less of the disclosure of the earlier filed copending application. The later application is called a continuation in part of the earlier application, such continuation in part being thus an application part of the disclosure of which is contained in an earlier filed copending application and part of which disclosure is not contained in the earlier filed application. This later application may contain claims to matter disclosed in the earlier application. As to such claims, the applicant is entitled to the filing date of the earlier application, and as to claims directed to matter disclosed only in the later application, the applicant is entitled only to the filing date of such later application.

Interferences. An *interference* is a proceeding instituted in the Patent Office for the purpose of determining the question of priority of invention between two or more parties claiming substantially the same patentable invention. If two applicants claim the same invention in their respective applications, the Patent Office institutes an interference to determine which of the two made the invention first and grants the patent on the common invention only to him whom the Patent Office considers to be the first inventor.

An applicant may obtain an interference and contest priority of invention with a patentee. The applicant must, however, unless he was claiming the patented invention at the time the patent issued, copy in his application the claim or claims of the patent upon which he wishes to contest priority within 1 year of the grant of the patent. He must at the same time identify the patent and show how the disclosure in his application warrants the making of the patent claim. In case the applicant wins the interference, the Patent Office, although it cannot cancel the patent which it has already granted, will grant him a patent on the common subject matter.

An interference proceeding is highly technical and at times very complicated, and anyone who finds himself involved in interference is advised to employ a competent attorney to represent him.

Allowance. When all claims in an application have been allowed and all formal requirements have been complied with, the application is said to be in condition for allowance, and a notice of allowance is sent to applicant in which he is given 6 months in which to pay the final fee of $30 for 20 or less allowed claims and $1 for each claim in excess of 20, except in design applications for which there is no final fee.

A matter of several weeks elapses between the receipt of the final fee and the grant of the patent. The Patent Office acknowledges receipt of the final fee and informs applicant of the number of the patent and the date it will be issued, whereupon the patentee, his assigns, or legal representatives making or selling any such patented article should mark the same with the word "Patent" together with the number of the patent.

Except during interference proceedings, where the rules permit one to inspect his opponent's application, pending original applications are preserved in secrecy in the Patent Office.

CLASSES OF PATENTABLE INVENTIONS

To be patentable the subject matter of an invention must fall within one of the following statutory classes: art, machine, manufacture, composition of matter, plant, or design. Anything falling within these classes to be patentable must also satisfy the test of novelty, utility, and invention.

Art or Process. An art, by which is meant a process or method, consists of an act or series of acts performed on some subject matter to reduce or transform it to a different state or thing. As a process it must be one which can be employed independently of any particular mechanism for carrying it out, as, for example, where one or more steps of the process may be performed by hand. The result produced by the process must be a physical result, and while it often produces a permanent change in the physical state of an article or composition of matter, it need not do so necessarily. Thus, a method of transmitting speech by causing the flow of electrical undulation corresponding to the sound of the human voice was held patentable.

Also, while most processes involve chemical or other elemental action or involve the employment of forces producing physical change such as heat, light, electricity, and the like, certain methods which involve only mechanical operations have been held patentable.

In a greater part of the field of human endeavor, activities will arise which display ingenuity and novelty and are productive of useful results but are not properly the subjects of patent protection. For example, methods of doing business, systems of bookkeeping, plans of military strategy, and the great mass of activity dealing with human relations are not such arts as are properly the subject of patents.

Machine. A machine is a combination of mechanical parts adapted to receive energy and apply it to the production of some energetic result. It includes any device having moving parts by which energy may be utilized or a useful operation can be performed.

Manufacture. A manufacture or article of manufacture is anything made by the hand of man which is not a machine or composition of matter. This has been held to include building structures.

Composition of Matter. A composition of matter covers all compositions or mixtures of two or more substances, whether the result is chemical union or mechanical mixture or whether they be gases, liquids, powders, or solids. Such a mixture or composition should have properties which are different from or in addition to those possessed by the several ingredients in common A new chemical compound is patentable, and a new mixture of old compounds may be patentable if it produces a new result. This class also includes composite articles.

The distinctions between machines, manufactures, and compositions of matter are not always clear, but an inventor need not know to which of these classes his invention belongs so long as it falls within the field covered by them all.

Plant. The statute provides that anyone who has discovered or invented and asexually reproduced any distinct and new variety of plant other than a tuber-propagated plant may patent the same under conditions which obtain for mechanical patents.

Design. A design is the characteristic of an article which by means of lines, images, configuration, or the like taken as a whole makes a visual impression of uniqueness or distinctive character, and such design, in order to be patentable, must be ornamental.

The article to be the subject of a design patent must have a purpose which is primarily utilitarian. If the purpose is primarily ornamental and not utilitarian, it may, however, be entitled to copyright protection.

NOVELTY AND UTILITY

In order to entitle one to a patent, the invention which he has produced must be new and useful (Revised Statutes, sec. 4886).

Novelty. *Knowledge and Use.* To be new an invention must not have been known or used by others in this country before his invention or discovery thereof, and it must not have been in public use or on sale in this country for more than 1 year prior to his application for patent.

Prior knowledge to defeat a patent must be knowledge of something substantially identical with that for which a patent is sought. It must be more than a mere concept of the invention; it must be knowledge of the thing itself in its concrete operative form. Knowledge "by others" does not mean that such knowledge must be shared generally by the public. It is sufficient if such knowledge was accessible to the public.

The knowledge, use, and sale to constitute a bar must be in this country. But knowledge in this country of use or sale in a foreign country is no bar to the grant of a patent in this country.

Patented and Described. Also, to entitle one to a patent the invention must not have been patented or described in any printed publication in this or any foreign country before his invention or discovery thereof or more than 1 year prior to his application. The printed description to constitute an anticipation must disclose a complete and operative invention in such full, clear, and exact terms as to enable one skilled in the art to which the invention relates or to which it is most nearly related to practice the invention.

Utility. An invention to be patentable must be *useful.* The term is used in contradistinction to frivolous. In point of fact, any utility, however slight, is sufficient to satisfy this requirement. To be patentable the invention must not be mischievous or immoral. A new chemical compound as such may be presumed to be useful, but invention must be involved in its production. There is no statutory requirement of utility for a patent for a design invention.

INVENTION

In the great majority of cases the thing that an applicant describes in his patent application and claims as his invention will differ in some or many respects from anything which had previously been described in any printed publication or was before known or in public use or on sale. In other words, it will differ from anything comprised within that body of material which is known as *prior art.* This does not mean that because of these differences what is claimed is patentable. The differences must be such as to require the exercise of the inventive faculty on the part of one skilled in the art to which the invention pertains in order to reproduce, from the mass of information contained in the prior art, the thing that the applicant devised.

Certain negative rules are applied as a test for invention. For example, a mere change in materials does not generally amount to invention. Thus, if one substitutes for the material of which a part was composed a material which was known to be stronger and more durable and thereby produces a part which is merely stronger and more durable, no invention is involved. On the other hand, sometimes a change in material produces a result which is unexpected and in certain cases brings into use an otherwise unrecognized property of the new material in which case the substitution may involve invention.

Also, it has been held that a mere change in form or proportions or degree does not involve invention. This is because one skilled in the art could readily foresee what result would be produced by such a change. But here again, an unforeseen result may show invention.

A common instance of change in proportions conferring patentability occurs in compositions of matter, as in metal alloys, many of which have been patented. The prior art may show a composition having substantially the same ingredients but in proportions different from those of applicant. It may also be found that, as the proportions are changed, when they depart from those of the prior art and approach the proportions disclosed by applicant, certain unexpected and useful properties are developed in the composition. This is an indication of invention, and the proportions in such case are termed *critical.*

Similar rules of noninvention apply where the change is in location of parts, mere duplication or reversal of parts, making parts integral when formerly separate and vice versa, and adding parts without producing a new and unexpected result.

Also, when a part is omitted from a combination of elements and the sole change produced is the omission of function of that part, no invention is involved, although the omission of a part and rearrangement of the remaining parts so as to perform its function may be a patentable invention.

Invention in Designs. The test of invention for a design patent is the same as for a mechanical patent, *viz.*, whether the design was beyond the powers of an ordinary designer.

PATENTED ON FOREIGN APPLICATION

A further statutory requirement for the grant of a patent is that it must not have been patented by the inventor or his legal representatives or assigns in any foreign country on an application filed more than 12 months (or 6 months in the case of designs) prior to the filing in this country. If the foreign application was filed within 12 months of the filing in this country (or 6 months in the case of designs), the granting of the foreign patent does not constitute a bar to the grant of a patent in this country. Even if the foreign application was filed more than 1 year prior to the filing in this country, the granting of a foreign patent to applicant after the granting of the United States patent does not affect the validity of the United States patent.

ABANDONMENT OF INVENTION

A further requirement for the grant of a patent is that the invention shall not have been abandoned. This occurs by an express declaration of abandonment or relinquishment of a completed invention to the public or by acts or omissions from which an intention to abandon may be inferred. An abandonment of the invention should be distinguished from the abandonment of a patent application, which usually results from failure of an applicant to take timely action in the prosecution of the application as has heretofore been explained.

Another matter should be mentioned here. One who makes an invention may, if he desires, practice it in secret, or he may patent it, in which case it is published to the world. He may not, however, practice it in secret until knowledge of the invention has been acquired by others and then patent it. If one practices an invention in secret until he discovers someone else has entered his field, any patent which he applies for subsequently will be invalid.

DATE OF INVENTION—INTERFERENCES

It frequently becomes necessary for an applicant or a patentee to establish by evidence the date when he made his invention or discovery.

For example, among the statutory requirements for the grant of a patent as above given is that the invention shall not have been described in a printed publication before his invention or more than 1 year prior to his application for patent. If during the prosecution of the application the patent examiner discovers a publication describing the invention and such publication is dated more than 1 year prior to the application, the examiner will call the applicant's attention to the publication and reject the claims of the application thereon, and such publication will constitute an anticipation of the invention. If, however, the publication antedates the application by less than 1 year and does not antedate the completion of the invention, it is not a bar to a patent. The examiner rejects in such case because he has before him as evidence of the date of invention only the application, and in the absence of other evidence, the filing date of the application is deemed to be the date of invention. In reply to such rejection the applicant may submit proof that he made the invention before the date of the publication, and if he does this the examiner will withdraw the publication as a reference.

Another instance where it is necessary to establish a date of invention is where two or more applicants file separate applications, all claiming the same invention. In this case the Patent Office grants a patent covering the common subject matter only to the one who first made the invention, this being determined in an interference proceeding.

In the development of an inventive idea into a concrete embodiment there is often considerable work involved. If the invention is a machine or other device, sketches will often be made, and later a model may be constructed. If the invention is of a chemical nature, experiments may be conducted or samples made and tested to see if the desired results are produced. Either during or after this preliminary work the inventor may file an application for patent, and it becomes important to determine at what point in this activity the invention is considered legally to have been made, *i.e.*, to have been completed in the sense of the patent law.

The general rule is, subject to one exception, that the invention is considered made when it is shown to be complete, and, in general, that is not until it is reduced to practice. *Reduction to practice* is of two kinds—*actual* and *constructive.*

Actual Reduction to Practice. Actual reduction to practice consists in the production, constructing, or building of an embodiment of the invention and the successful testing or operating of such embodiment under conditions actually met with in practice. In certain cases of very simple inventions, where successful operation can be determined from mere inspection of the embodiment, it has been held that proof of test is unnecessary.

Constructive Reduction to Practice. Upon filing an application containing an adequate disclosure of an invention, the applicant is thereafter entitled to the benefit of the filing date of such application as a constructive reduction to practice of whatever is disclosed. He is also entitled to the benefit of the filing date of a copending application containing a disclosure of the invention or of any previously filed application not then pending, provided there was continuously, from the date relied upon, some application pending which contained a disclosure of the invention. An inventor is also entitled to the benefit, for constructive reduction to practice, of the filing date of a foreign application filed by him or his legal representatives or assigns and which discloses the invention, provided the same was filed less than 12 months (6 months in the case of designs) prior to the filing in this country. The benefit of a foreign filing date is given the applicant under a treaty or international convention (known as the International Convention for the Protection of Industrial Property), and a United States application filed within 1 year of the filing of a corresponding foreign application is said to be *filed under the convention.*

The exception to the general rule that to show prior invention one must show reduction to practice, either actual or constructive, is the case frequently arising in ex parte and inter partes proceedings in the Patent Office and in the courts where prior conception is shown by the applicant or patentee accompanied by diligence from the date of the anticipation or bar asserted against him continuing until his own reduction to practice or, in the case of an interference with another inventor, conception prior to that of the other's invention accompanied by diligence continuing without interruption from the time the other inventor entered the field to the date of his own reduction to practice.

From the above it will be seen that it is advisable that an inventor keep a current record of his activity in the development of an invention. He should write a description of the invention as soon as possible, accompanied by drawings, if the invention can be illustrated by drawings, or by examples, both dated and witnessed by someone who understands the invention. A record should be made of the date of conception, the time and place of the first disclosure to others, the making and disclosure of the first sketch and description, the completion of a model or full-size device, tests of the device and results of the tests, extent of the invention's use, and the dates of any applications filed.

OWNERSHIP AND ASSIGNMENT

Ownership. A patent is personal property and may be owned by one or any number of persons. Each of several owners has an undivided interest in the patent, and while such ownership is called "joint," it is more nearly an ownership in common. On the death of such joint owner, his undivided interest passes to his legal representatives. When a patent is granted to two or more joint inventors each becomes a joint owner. To be an owner of a patent jointly with someone else has its disadvantages.

One of two joint owners is to some extent at the mercy of the other. The other can practice the invention, can make, use, and sell a device covered by the patent without accounting to the first owner and license others to make, use, and sell without accounting to the first owner for any royalties received. And this is true no matter how small the other's undivided interest may be, in the absence of an agreement between them providing otherwise.

Assignment. By statute any patent or patent application or any interest therein is made assignable by an instrument in writing, and by such an assignment the exclusive right under the patent may be granted to the whole or any specified part of the United States, the latter being termed a "territorial grant." The assignee in each case should have the written assignment recorded in the Patent Office in Washington, as the law provides that an assignment shall be void against a subsequent purchaser for value without notice unless recorded within 3 months from the date of the assignment or before the subsequent purchase.

If an assignment is acknowledged before a notary public or other officer specified by law, who affixes his official seal, such acknowledgement is prima facie evidence of the making and delivery of the assignment.

One may assign all right, title, and interest in and to a patent, or he may assign one-half, one-third, or any other fractional undivided interest. Where a sharing of profits or royalties among coowners is desired, provision for such sharing should be made by contract.

EXTENSION AND REISSUE OF PATENTS

Extension. The term of a patent can be extended only by act of Congress. A few patents were extended after the First World War, but it is not the policy of Congress to extend patents and has not been for many years.

Reissue. A *reissue patent* may be granted for the unexpired term of a patent already granted when such patent is inoperative or invalid by reason of a defective or insufficient specification or by reason of the patentee claiming as his own invention more than he had a right to claim as new if the error arose by inadvertence, accident, or mistake and without any fraudulent or deceptive intention.

The word "inoperative" as here used, means inoperative to protect the patentee. Thus, if the specification of the patent describes two inventions both of which might have been claimed but only one was claimed, the patent is inoperative to protect the inventor in respect to the other invention.

The statute requires that the reissue patent shall be for the "same invention." By this is meant whatever invention was described in the original patent and appears therein to have been intended to be secured thereby.

An application for reissue must be made by the inventor if living and, if assigned, must be accompanied by the written assent of the assignee. It must be accompanied by the original patent with an offer to surrender the same on grant of the reissue, and the oath accompanying the reissue, in addition to the averments of the oath in the original application, should point out the defects or insufficiency of the specification of the original patent or how the patentee claimed more than he had a right to claim and should specify the inadvertence, accident, or mistake from which the error arose.

Where the claims sought in a reissue application are broader than those of the original patent, the reissue must be applied for promptly—except in most unusual circumstances within 2 years at the most of the grant of the original patent. Where, however, the claims of the reissue are more specific than those of the original application, it is sufficient if the reissue is applied for promptly after the discovery of the inoperativeness or invalidity of the original.

INFRINGEMENT

An infringement of a patent is the unauthorized making, using, or selling of an embodiment of the invention. In the case of a process, it is infringed by him who without ownership or license uses substantially the process of the patent. Actual knowledge of the patent by the infringer is not required provided the patentee has given the notice called for by the statute by marking his invention with the patent number, in default of which damage for prior infringement cannot be collected.

The measure of the monopoly of a patent is the claim or claims of the patent, and to be an infringement there must be a claim of the patent which is infringed. If what has been done or what has been made or used or sold is correctly described in the entire claim of a patent, if each element of the claim is present in the process performed or the thing that is made, used, or sold and is present in the relationship set forth in the claim, such claim is infringed. If for example, a claim contains three elements, those three elements or their equivalents must be present in the infringing structure. By "equivalent of an element" in a claim is meant something which performs the same function as the element and in substantially the same way.

COPYRIGHTS

BY SHELDON H. GRAVES

HISTORICAL

At common law before the invention of printing the works or writings of an author belonged to the author. After the adoption of printing, writings were reproduced in quantities and distributed to the public, the works became public property, and the author was without recourse until 1710 when an English statute gave to authors or their assigns the sole right of publication for a limited period.

The granting of copyright in the United States is under federal statute enacted under authority of the Constitution. The Constitution provides that Congress shall have power to secure for limited times to authors the exclusive right to their writings.

WHAT MAY BE COPYRIGHTED

"Writings" as used in the Constitution has been held to include all forms of writing, engraving, printing, and etching by which ideas of the author are given visible expression. The ideas expressed need not display any high degree of artistic merit. It is not necessary that the materials be new but may include compilation of known facts or data. Music is included as well as pictorial illustrations, photographs, and advertisements.

By act of Congress the author must specify to which of certain designated classes the works for which copyright is sought belongs, but an error in assigning the work to some particular class is not generally fatal.

The **statutory classes** are as follows:

1. *Books, including composite and cyclopedic works, directories, gazetteers, and other compilations.* The book need not be a bound book but may be a single sheet, leaflet, or folder. It may consist merely of tables of figures. It, however, does not include slogans or mottos which are not copyrightable. A compilation includes selected extracts from different authors.

2. *Periodicals, including newspapers.* Each number of a periodical should be separately copyrighted.

3. *Lectures, sermons, and addresses* (prepared for broadcasting or oral delivery). This includes unpublished manuscripts; when published these should be registered as a book.

4. *Dramatic or dramatico-musical compositions.* This includes plays, operas, and oratorios.

5. *Musical compositions.* This includes songs with words and music written in any notation but does not include perforated music rolls or phonograph records. However, the owner of a copyright on the composition can control the production of such rolls and records.

6. *Maps.* When accompanied by text maps should be copyrighted as a book.

7. *Works of art, models or designs for works of art.* Includes paintings, mosaics, carvings, statuary, plaques, and bric-a-brac. Where the artistic appearance is applied to articles of manufacture which have primarily a utilitarian purpose such as clocks, furniture, rugs, etc., the article is patentable as a design but cannot be copyrighted.

8. *Reproduction of works of art.* Includes sketches, photographs, or etchings of original works of art such as paintings or sculptures.

9. *Drawings or plastic works of a scientific character.* Includes anatomical figures and also stock-market charts.

10. *Photographs.* Includes photographs which embody artistic conceptions and also the mere mechanical reproduction of the appearance of any object.

11. *Prints and pictorial illustrations.* Includes illustrations of anything and mere decorative features such as an artistic border for a stock certificate. This class also includes commercial prints and labels for articles of merchandise.

12. *Motion pictures, photoplays.* Includes photoplays whether accompanied by sound or not. Also so-called shorts.

13. *Motion pictures, other than photoplays.* Includes educational films and newsreels.

Commercial prints and pictorial illustrations were until recently registered in the Patent Office but are now registered with the Register of Copyrights in the Library of Congress. A commercial print is an artistic work with or without text published in a periodical or separately in connection with the sale or advertisement of an article or articles of merchandise. A label is an artistic or literary work attached to an article of merchandise or to containers therefor to indicate the nature of the goods.

Such a print or label to be copyrighted must first be published by the proprietor or under his authority with notice of copyright claim on the copies. Publishing means placing on sale, selling, or publicly distributing. The notice must be on each copy published or offered for sale in the United States. The notice of copyright may consist of the word "Copyright" or "Copr." on every label or print followed by the name of the proprietor or may consist of © in accordance with requirements hereafter noted for this type of notice. Two copies of the label or print must be deposited with the Copyright Office and the statutory fee of $6 paid. The application for copyright should be made on the form furnished by the Copyright Office.

MATTER NOT COPYRIGHTABLE

The following are not copyrightable: checks, vouchers, business forms, the original text of any work in the public domain, except compilations thereof, and government publications, mere ideas or plans, and seditious, libelous, fraudulent, immoral, and indecent works. The title of a work is not copyrightable, but where the copying of a title results in unfair competition, relief may be had on this ground aside from any copyright protection. In some cases titles may be registered as trade-marks.

WHO MAY SECURE COPYRIGHT

Copyright may be obtained by the author, his executors, administrators, or assigns. When the copyright or the right to obtain a copyright is assigned, the assignee becomes the "proprietor" and is entitled to the copyright. In the case of *ghost writers*, the ghost is generally the one entitled. Where one writes for hire, the employer is the proprietor and entitled to the copyright.

The person entitled to the copyright must be a citizen of the United States or, if a foreigner, must be domiciled within the United States or a citizen of a so-called "proclaimed" country designated as such by proclamation of the President. A "man without a country" is entitled to a copyright.

STATUTORY REQUIREMENTS FOR OBTAINING COPYRIGHTS

A copyright is secured by publication with notice of copyright.

A work is published when the first authorized edition is "placed on sale, sold, or publicly distributed by the proprietor of the copyright or under his authority." From this quotation it would appear that the mere showing of a picture or motion picture is not a publication as required by law. A motion picture therefore would not be published until it is distributed. It is important to note that the publishing with notice of copyright precedes the application for copyright registration and that publication without such notice constitutes an abandonment of the claim of copyright.

The notice required consists of the word "Copyright" or "Copr." accompanied by the name of the proprietor; in the case of a literary, musical, or dramatic work comprised in classes 1 to 5, inclusive, and the notice must be accompanied by the year. However, in case of copies of works specified in classes 6 to 11, inclusive, the notice may consist of ©, followed by the "initials, monogram, or mark or symbol of the proprietor," provided on some accessible portion of the copies or of the margin, back, permanent base, or pedestal or of the substance on which such copies shall be mounted, his name shall appear.

This notice must be applied (1) in the case of a book or other printed publication upon the title page or the page immediately following; (2) if a periodical, either upon the title page or upon the first page of text of each separate number or under the title heading; or (3) if a musical work, either upon the title page or the first page of music. For a contribution to a periodical, it may be placed under the title or, if all on one page, at the end of the article.

Promptly after publication, two copies of the best edition of the work must be deposited in the Copyright Office together with the application for copyright which may be made out on a form furnished by the Copyright Office. Except in the case of the original text of a book of foreign origin or authorship and in a foreign language, the typesetting, printing, and binding of copies deposited of a book or periodical must be within the limits of the United States, and the application must be accompanied by an affidavit to that effect, a form for which affidavit is furnished by the Copyright Office.

The application for registration should be accompanied by the statutory fee of $2 except for a print or label published in connection with the sale or advertisement of an article of merchandise, where the fee is $6, and of unpublished work and a photograph where no certificate is demanded, where the fee is $1.

INTERIM REGISTRATION

Provision is made for interim registration of foreign books pending printing in this country.

TERM

The term of a copyright is 28 years. The law provides for a renewal by certain specified persons for a renewed term of 28 years.

RIGHTS SECURED BY COPYRIGHT—INFRINGEMENT

As provided in the Copyright Act of 1909, as amended, the copyright owner has the exclusive right

> *Sec.* 1 *a*: to print, reprint, publish copy, and vend the copyrighted work. . . . A copy, is that which comes so near the original as to give to any person seeing it the idea created by the original.

It need not be a word-for-word copy. It may be copied in a different medium as showing a photograph on a screen. The copying of a substantial part of the original is an infringement. However, one may make a fair use of a copyrighted work. The copyright owner alone has the right

> *Sec.* 1 *b*: to translate the copyrighted work into other languages or dialects or to make any other version thereof if it be a literary work.

Versions include abridgments or telling the story in other words, but a mere sketchy outline would be a "fair use" and not an infringement.

> *Sec.* 1 *b* (2): to dramatize it if it be a nondramatic work.
>
> *Sec.* 1 *b* (3): to convert into a novel or other nondramatic work if it be a drama.
>
> *Sec.* 1 *b* (4): to arrange or adapt it if it be a musical work as an arrangement for an orchestra or to change the key or pedaling.
>
> *Sec.* 1 *b* (5): to complete, execute, and finish it if it be a model or design for a work of art.

These are works of the fine arts rather than industrial arts which are covered by the patent law.

> *Sec.* 1 *c*: to deliver or authorize the delivery of the copyrighted work in public for profit if it be a lecture, sermon, address, or similar production.

By *similar production* is meant a production intended in the first instance for oral communication.

> *Sec.* 1 *d*: to perform or represent the copyrighted work publicly if it be a drama [This provision also includes dramatico-musical works] or if it be a dramatic work and not reproduced in copies for sale, to vend any manuscript or any record whatever thereof. . . . [The performance or representation thereof need not be for profit]

This provision includes exhibition of motion-picture plays but does not include poems, as these may be recited in public without infringement.

> *Sec.* 1 *e*: to perform the copyrighted work publicly for profit if it be a musical composition. . . .

For profit does not mean that there must be paid admission to hear the music. The unauthorized broadcasting of a song in a radio program under a sponsor is infringement. The provision includes music with motion pictures.

There are certain exceptions from liability for unauthorized performance of music: (1) reproduction of music by coin-operated machines and (2) certain religious and secular works, even though an admission is charged, if the fee is applied to charitable or educational purposes.

> *Sec.* 1 *e* (continued): and for the purpose of public performance for profit and for the purpose set forth in subsection *a* hereof, to make any arrangement or setting of it (the musical composition) or of the melody of it in any system of notation or any form of record in which the thought of the author may be recorded and from which it may be read or reproduced.

In this section the reproduction from a phonograph or other record is not an infringement; the record itself is not a copy of the original composition, but the proprietor has the control of the manufacture of such records. The law, however, provides that, when the proprietor himself has used or sanctions the use in this way, anyone may make records on payment to the proprietor of 2 cents royalty for each record.

    - fire-insurance schedules, 174, 175

Fire protection and prevention, industrial-plant, cost accounting, fire-insurance schedules, conditions for, 176
    - fire-resistive construction, 183, 184
      - standard requirements for, 183, 184
  - dusts, explosive and flammable, 220–225
    - bronze dust, 224
    - coal dust, 223
    - dust-fire extinguishing, 220
    - explosion pressures, 221
    - explosion prevention, 222, 223
    - ignition of, 222
    - metal powder, 221–225
    - organic-dust flammability, 220, 221
    - plastics industry, powders used in, 225
    - sulfur dust, 224
  - equilibriums, 195
  - equipment for, 177
  - fire, 185–190
    - attacking of, 261
      - essentials for, 261
    - causes of, 225–243
      - air-conditioning ducts, 233
      - anaesthetic gases, 237
      - bearings, journal, 232, 236
      - belts, power transmission, 232
      - chemical reactions, 193
      - chimneys and flues, 233, 234
      - cutting operations, oxygen- and acetylene- 235, 236
      - dust explosions, 193
      - electric sparks, 193
      - electrical fires and their prevention, 225–230
      - electrostatic coating process, 240
      - exposure, 240, 241
      - flames, lights, and sparks, open, 232
      - focused rays 194
        - from glass bubbles, 233
      - friction, 236
      - gas, natural and artificial, 243
      - heating furnaces, 233
      - hot ashes and coals, 242
      - lightning, 193
      - oily waste, storage of, 231
      - ovens, and driers, 234, 235
      - overheated materials, 233
      - packing materials, storage bins for, 231
      - pipes for heating, steam, hot water, and oil, 241, 242
      - rubbish and litter, 236, 237
      - smoking, cigarettes, matches, 231
      - sparks on roof, fireproof roofing, 233
      - spontaneous ignition, 192, 230, 231
      - static electricity, 194, 195, 237, 238
      - welding operations, 235, 236
    - combustion of, 185–190
      - heat of, 187
      - oxidizing, 185
      - slow, 188
    - definition of, 185
  - fire prevention, 190–266
    - in building construction, 197–204
      - dry rot, effect and prevention of, 200, 201
      - exits, 200
      - fire ratings, 197
      - fire-resistance point, 197
      - floor area limits, 198
      - glass blocks, 199
      - height limits, 198
      - hurricanes, effect of, 200
      - openings, vertical, 203, 204
      - piers and wharves, 203
      - roofs, 199

Fire protection and prevention, industrial-plant,
      fire prevention, in building construction, termites, effect and prevention of, 201
      vertical separations, 203
      walls, 201–203
      water seepage and drainage, scuppers for, 204
      wired glass, 198, 199
    confining of fire, 197
    driers, lamp, infrared, 239
    electrical fires (*see* fire, causes of, above)
    electrostatic coating process, 240
    operations and processes, diagram of plant, 261
    process of, 191
    science of, 191
    self-inspection blank, 262–265
    static electricity, 237, 238
    stock-flow method, 261
  fire protection, 243–266
    alarm systems for, 259, 260
    automatic sprinkler systems, 252–258
      cost of installation of, 257, 258
      dry-pipe system, 257
      outside sprinklers, 256
      wet system, 251–256
    fire brigade, plant, 260, 261
    fire extinguishers, 244–247
      antifreezing solutions for, 245
      classification of, 244
      hazards when used on electrical equipment, 245
      location of, 244, 245
      weights of, 245
    fire-extinguishing systems, flammable liquids, 258, 259
      types of, 258, 259
    fire pumps, 250, 251
    hose houses and equipment, 248
    hydrants, yard, 248
    plant organization for, 243, 244
    standpipes, 247, 248
    watchman's duties in, 261
    water supplies, public and private, 249
  flammable liquids and gases, 204–220
    atmospheres, explosion- and fireproof (*see* inert gas systems, below)
      in tanks, 215, 216
    calorific value of, 206
    classification for, flammable liquids, 207
    commercial gases, calorific value of, 215
    degree Baumé of liquids, 206
    dip tanks, 212
    explosionproof electrical equipment, 207, 210
      (*See also* Motors)
    explosions, 210
      pressures for gasoline vapor and air mixture, 210
      venting, 210
    flame arresters, 214
    flammable gases and vapors, 217–219
      density, 217, 242
      diffusion, 217
      explosibility of, effects of inert gases and low-oxygen content on, 221
      explosive limits, 217–219
    gas masks, 219, 220
    hazardous locations, classification of, 207
    inert gas systems, carbon dioxide in, 220
    liquid petroleum gases, 216
    oil burners, 210
    physics of, 204–206

Fire protection and prevention, industrial-plant,
    flammable liquids and gases, pressure releases for flammable gases, 214
    refrigerants, 216, 217, 619
    sewer and manhole gases, 215
    solvent recovery, 211, 212
      equipment for, 211, 212
      methods of, 211
    solvents, 210
    specific gravity of liquids, 206
    spray booths, 212
    standards, NBFU, for flammable liquids, 214
    storage, above-ground, for flammable liquids, 213, 214
      underground, for flammable liquids, 213
    thermal expansion of flammable liquids, 206
    transportation of, 212, 213
    vapor pressure specifications, Reid's, 213
    ventilating for, 207
  heat, properties of, (conduction, convection, explosion, oxidation, radiation), 190
  inert gas in, 220
  plastics, flammability of, 224, 225
  reports, reference books, educational pamphlets, 196, 197
  sprinkler systems, automatic (*see* automatic sprinkler systems, above)
Fire-resistive building construction, 183, 184
Fire tower, 203, 204
Fire walls, 201–203
Fires, classification of, 244
  electrical, 226–230
    causes of, 226–230
Flame arresters, 214
Flame luminosity, 188
Flammability, limits of, 188
Flammable dusts, gases, liquids, and vapors (*see* Fire protection and prevention, industrial-plant)
Flash point lubricating oil, 1308, 1309
    (*See also* Fire protection and prevention, combustion)
Flaw detection by ultrasonic vibrations, 1679
Flax packings, 1353, 1354
Flexible couplings, 1069–1076
Flight conveyors, 1411
Float valve, diaphragm-packed, 1396
"Floating" bases for machines, mechanical-vibration control by, 1866
"Floating" floors, noise control by, 1866
Floating rate, instrumentation and control, 707, 709
Floating shafts, 1073, 1074
Floating speed, instrumentation and control, 703
"Floating" walls, noise control by, 1864
Floating wastes, water contamination by, 1589
Floor-area limits for fire protection and prevention, 198
Floor systems, concrete (*see* Concrete, reinforced)
Floors (*see* Construction, materials of)
Flow control, instrumentation and control, 679
Flow nozzles, 683
Flowmeters, pressure-lubricated, silicone lubricant for, 1345
Fluid drives, 1264–1283
  and brakes, shaft packings for, 1371
  constant-filling type of, 1264, 1275–1283
    applications of, 1264, 1275–1283
      commonly using, 1276, 1277
      electric motor, 1264
      internal-combustion engines, 1264, 1277–1283

Fluid drives, constant-filling types of, applications of, internal-combustion engines, hydraulic ratings based on engine torque, 1277, 1280, 1281
      mounting arrangements and figure, 1282, 1283
      rated torque at minimum engine rpm, table of, 1283
      selection of drive for, 1283
    arrangements of, commonly used, 1277
    dimensions, ratings, and weights of, tables of, 1278, 1279
    hydraulic ratings of, 1277
    operating principle of, 1275, 1276
  heavy-duty (PE) type of, duty classifications for, 1271
  medium-duty (VS) type of, duty classifications for, 1271
  variable-filling type of, 1264–1275
    variable-speed design of, 1264–1274
      enclosed, with speed controller, 1274, 1275
        design features of, 1274
        operating principles of, 1274, 1275
        speed-controller principle of, 1275
      lever-controlled type of, 1264–1269
        applications of, 1265–1267
        dimensions of, 1268, 1269
        hydraulic ratings for, 1265, 1266
        mounting arrangements for, 1266
        oil cooler for, 1269
        speed-control principle of, 1264, 1265
        torque ratings, variable and constant, tables of, 1265, 1266
      pump-controlled type of, 1269–1271
        arrangements of, 1271, 1272
        dimensions of, tables of, 1273, 1274
        hydraulic ratings for, 1269, 1270
        mechanical ratings for, tables of, 1273, 1274
        speed-control principle of, 1269
          (*See also* Transmissions, hydraulic)
Fluid friction (*see* Hydrodynamics)
Fluorescent lamps, 926
  Slimline and Circline types of, 928, 929
"Fluttering" of airplane wings and tails, 1830
Flux cutting by oxygen, 846
Flux removal, residual, in silver-alloy brazing, 825
Fluxes, in oxyacetylene welding, 832
  in silver-alloy brazing, 822
Foam system of fire extinguishment, 258
  flammable liquids, 258
Foamglas (*see* Construction, materials of; Glass specialties)
Food inspection by X rays, 1636
Food and kindred products, basic industrial costs of, 7–9
Foot-candle and foot-lambert, defined, 916
Footings (*see* Foundations)
Force-feed oilers for refrigeration compressors, 1333, 1334
Forced vibration, 1842

INDEX

- **Graphical mathematics,** nomographic or alignment charts, solution of equations by,
  - energy content for rectangular channel with uniform flow, 1734
  - equity debt, 1750
  - Fanning equation, pressure drop in pipe, 1746
  - Francis formula for contracted weir, 1735, 1736
  - gas analysis, excess air from stack, 1753
  - light radiation, net, 1716, 1717
  - means, various types of (arithmetic, geometric, harmonic, logarithmic), 1754
  - mol per cent–weight per cent, 1720, 1721
  - moment of inertia of rectangular plate, 1727
  - stability number for infinite slope in homogeneous soil, 1732
  - triangles, solution of, by law of tangents, 1720, 1722
  - velocity of flow of water, Chezy formula, 1720
  - weir, contracted, Francis formula, 1735, 1736
    - rectangular suppressed, Rehbock formula, 1750, 1751
- quadratic, cubic, and biquadratic equations, 1709–1713
  - biquadratic equations, 1712, 1713
    - resultant cubic, 1713
  - cubic equation, 1710–1712
    - complex roots, 1710, 1712
  - quadratic equation, 1709, 1710
    - complex roots, 1710
- Simpson's rule, 1787, 1788
  - area under curve, 1787, 1788
  - definite integral, approximate value of, 1787
- single variable, solution of equations containing, 1713–1715
  - approximate solution of, 1713–1715
- variables, graphical method for charting relationship between, basic form of, 1781–1787
  - network, addition of, 1787
- Graphical representations of functions (*see* Graphical mathematics)

    condensing vapors, 1615
    natural convection, 1615
    scale deposits, 1617
    streamline flow, 1615
    turbulent flow, 1614, 1615
  heat exchangers, 1612, 1613
    steam condensers, 1613
  nomenclature used in, 1606, 1607
  radiation, 1606, 1610–1612
    angle factor of, 1610–1612
    definition of, 1606
Heat-transfer properties of materials, 1618–1622
  emissivity, 1621, 1622
    total, of miscellaneous materials, table of, 1621
    variation of, 1622
      surface, nature of, 1622
      surface treatment, 1622
      temperature, 1622
  thermal conductivity, 1618–1622
    of miscellaneous materials, table of, 1619, 1620
    variation of, 1618–1622
      density, 1618
      mean temperature, 1618
      mixture of materials, 1622
      moisture, 1620
      pore size, 1620, 1622
Heat-transfer rate of metal surface to air, 753
Heat transmission, coefficients of building materials, table of, 1479–1482
  solar, 1483
  through structures, 1478
Heating, dielectric and induction, 1665–1669
Helical gear reducers, (*see* Gear-reduction units)
Helix element, instruments, 681
Hercules benzyl cellulose, 1935
Herringbone gear reducers (*see* Gear-reduction units)
Hexagonal chart, graphical mathematics, 1708, 1709
High-acetyl acetate, 1934
High-carbon steel, oxygen cutting of, 847
    flame softening as heat-treatment in, 847
Hoists and grabs, 1418
Holzwarth turbine, 466
Horco X, 1932
Horsepower, defined, 1459
Hose houses and equipment for fire protection, 248
Hot-rolled steel shafting, 989, 990
Houdry process, gas turbines for use in, 468, 469, 489, 490, 499, 500
    turbine installation, 488
Hour, actual and standard (*see* Incentive wage)
Hulett boat unloader, 1406
Humidifiers for air-conditioning systems, 1500, 1501
  air-washer-spray type of, 1500
  filter-washer type of, 1500, 1501
Humidity, absolute, 1463
  control of, 721
Humidity, electric measurement of (*see* Instruments, electrically actuated)
  percentage of, 1464
  ratio of, specific, 1463
  relative, 560, 1463, 1464
"Hunting" of automatic control systems, 1830
Hydrants for fire protection, 248
Hydraulic-accumulator packing, 1367, 1368
Hydraulic ash-handling system (*see* Ash handling)
Hydraulic-circuit design and evaluation check list, 1301, 1302
Hydraulic couplings (*see* Fluid drives)
Hydraulic-cylinder packing, 1294
  packing for oil hydraulic or oildraulic cylinders, 1368
Hydraulic-intensifier packing, 1368
Hydraulic motors, power equipment, and transmissions (*see* Transmissions, hydraulic)
Hydraulic-ram packing, 1367
Hydraulic-transmission pumps (*see* Transmissions, hydraulic pumps)
Hydraulics, applications of, 1302
Hydrochloric acid recovery from plant wastes, 1594
Hydrodynamics, 1286–1290
  fluid friction, 1287
    hydraulic piping, 1287
      pipe-line velocities, 1287
        head loss in pipe lines, 1287
        pressure drop through orifice, calculation for, 1287
        Reynolds number, 1287
  kinetic energy of mass in motion formula, 1286
  velocity head, formula, 1286
  venturi effect, 1286, 1287
Hydrofluoric acid in plant wastes, neutralization of, 1596
Hydrogen atom, Bohr's model of, 1639
Hydrogen gas in tanks in fire protection and prevention, 216
Hydrogen spectrum, 1639
Hydrostatics, 1284–1286
  energy, 1285, 1286
    elastic, of fluids, 1285, 1286
    in fluids at rest, 1285
    pressure, 1285
  multiplication of forces, Pascal's theorem of, 1285
    equality of pressure of liquids, 1285
  pressure, defined (absolute, atmospheric, gauge), 1284
    pressure measuring methods, 1284
  pressure head, defined, 1284
  pressure head–pressure relation formula, 1284, 1285
  suction head, defined, 1285
    importance of, 1285
Hygroscopic materials, defined, 1471
Hyperbola, 1692, 1693
  tangent at point *P* on, construction of, 1693
Hyperbolic curves, 1796
Hypoid gear reducers (*see* Gear-reduction units)

I

Iceland-spar polarizer, Nicol prism, 1651
Idlers, for belt conveyors (*see* Belt conveyors)
  for chain drives (*see* Chain drives)
Ignition point, 188
Illumination levels, various, lighting for, 927, 928
Immersion tests (*see* Corrosion)
Impact machinery, vibration control for, 1854–1858
    spring-isolated hammer foundation, 1856

        packer for valve bags, 1693
        telemetering (see Power measurement,

Incandescent-filament lamps, 925, 926
Incentive wage methods, 60–78
  apprentices, 69
  clerical workers, 69, 70
  direct workers, 68–70
  earning curves, 61–68

Industrial cost reduction, basic (*see* Cost reduction, basic industrial)
Industrial costs, basic (*see* Costs, basic industrial)
Inert gas, arc welding by, 795
  carbon dioxide in inert gas system, 220
  dust fire extinguishing by, 220
  metal-powder production use of, 222
Infrared rays, 1644–1650
  applications of, industrial, 1649
      surface finishing by, 1649
      therapeutic use of, 1649, 1650
  equipment for use of, industrial, 1646–1649
      infrared reflector, 1646, 1647
        coefficients of reflection for materials for, 1647
  infrared generators, gas-fired, 1646
    application of, 1646
  infrared installation planning, 1647, 1648
  infrared lamp spacing, 1648, 1649
  infrared lamps, types of, 1645, 1646
    nature of, 1644, 1645
    source of, industrial, 1645
Infringement, of copyright, 1954, 1955
  of patent, 1951
Ingot iron (Toncan iron), properties of, 1579
Injector conveying system, pneumatic, 1512
Instrumentation and control, 675–725
    cost accounting aided by, 677
    instrumentation, 676, 723–725
      costs of, 723–725
      scope of, 676
    measurements, basic criteria of, 681
    plant safety aided by, 678
    process variables, 678–681
      energy variables (pressure, temperature), 678, 679
      measurement of, 681
      quantity and rate variables (flow, liquid level, speed, thickness, weight), 679
      substance property variables (calorific value, chemical composition, color, density and specific gravity, electrical conductivity, explosibility and flammability, humidity, moisture content, pH or hydrogen-ion concentration, thermal conductivity, viscosity and consistency), 679–681
    product quality affected by, 677
    product testing by, 678
    savings effected by, fuel and materials, 677
  and metering, 411, 881

Instruments, 681–694
  electrically actuated, 684–694
    electric changes, elements for creation of,

      dropping mercury electrode, polarograph, 689, 690
      electric humidity measurement, 690
      electronic dew-point recorder, 690, 691
      infrared spectrometer, 693, 694
      moisture-content measurement by electrical conductivity, 691
      oxidation-reduction potential, 688, 689
      pH measurement, electrode assemblies for, 688
      resistance thermometers, 687
      thermocouple, 686, 687
      thermopile, 687
      ultraviolet spectrometer, 692, 693
      X-ray diffraction spectrometer, Geiger-Mueller counter tube, 692
    instruments for measurement of, 685, 686
      deflectional-type millivoltmeter, 685
      null-balance potentiometer, 685
  graphic (*see* Power measurement, graphic)
  indicating, damping of, 1801, 1802
  pressure-actuated, 681–684
    pressure changes, elements for creation of (bubble pipe, flow nozzle, manometer, orifice, thermometer bulbs, venturi), 681–684
      elements for measurement of (bellows and compensated-bellows, bourdon tube, helix, manometer–electrical and mechanical, spiral), 681
  recording (*see* Power measurement, graphic, graphic meters)
  sound analyzers and sound-level meters, 1813
  spring mounting of, vibration control by, 1808, 1809
  vibration problems solved by, 1842–1844
    acceleration-measuring, 1843, 1844
      accelerometers, 1844
    frequency-measuring, 1843
      stroboscope, 1843
      tachometer, Frahms type, 1843
    vibration-measuring, 1805, 1843
      "seismic" vibrometer, 1843
      vibrograph, 1843
Insulation, 748–769
  application of, 768, 769
  conductivity of, defined, 754
  85 % magnesia block, 759–761
  Foamglas, 1913, 1914
  heat losses, due to lack of, 748–753
      coal waste, 751
      surface temperature as unreliable measure of, 761
      theory of, 751, 752
    from heated surfaces, 748
  heat-transfer rate, metal surface to air, 753
  heat-transmission rates through sectional, table of, 772
  maintenance of, 768, 769
  monetary value of, 748–751
  pipe, 748–775
    application of, 768, 769
    blanket type of, 770, 771
    hanger details, 773–775
      pipe and hanger spacing for insulation application, 773, 774
    losses due to lack of, 754–759
      air velocity effect on bare surfaces, 754
      heat loss from bare surfaces, tables of, 755–759

Insulation, pipe, losses due to lack of, heat loss from bare surfaces, heat losses and savings, 85 % magnesia block, 759
      test data on, and theory of, agreement of, 752, 753
    low-temperature pipe-insulation advantages, 769–775
    maintenance of, 768, 769
    sealing of, 771, 774, 775
    sectional type of, 771
    selection of, 765, 767
    shield (saddle) details, 774
    sweating and frosting prevention by, 770
    thicknesses of, economical, 766–768
      chart for determining, 766
      typical economical thicknesses, 767, 768
    types of, available, 761–763
      thermal conductivity of, table of, 762
  roof, 156
  savings with, 753–761
  selection factors of, 763, 764
  thicknesses of, 764–768
    economical, chart for determining, 766
    selection of, for heat saving, 764–767
    typical economic, 767, 768
Integrals, definite, evaluation by nomograms of, 1792–1794
    charts for integrals, 1792–1794
    Simpson's rule for finding approximate value of, 1787, 1788
  evaluation by areas of, 1789–1791
    derivative curve, 1789, 1791
    integral curve, 1789, 1791
    mean ordinate determination, 1789, 1791
Integration, graphical (*see* Graphical mathematics)
Intensifiers, impeller, for hydraulic transmissions (*see* Transmissions, hydraulic)
Interferences, patent application, 1946
Internal-combustion engines, fluid drives for, 1277–1283
  piston packing for, 1368
  shaft packing for, 1371
    radial and split-radial seals for, 1371
  torsional vibration in, 1825, 1826
    methods for overcoming, 1825, 1826
      Lanchester damper, 1825, 1826
Inventions, 1949
  abandonment of, 1949
  date of, 1949, 1950
    interferences in, 1949, 1950
  development record value of, 1950
  patentable, 1946–1948
  priority of, 1946
  secret practice of, 1949
Inventory control of material, 285–287
Iodine absorption, spontaneous ignition, table of, 232
Ion-interchange tanks, rubber-lined, 7[illegible]
Ionization produced by X rays, 1632
Iron products, basic industrial costs of, 16
Iron removal from water, 302
Isolation efficiency, vibration, 1842, 1844–1847
Isotopes (*see* Radioactivity; X-ray therapy)

Jaw crushers (*see* Crushing)
Jet-propulsion units, aircraft, gas turbines for, 516–518
Job analysis, maintenance, 279–284
Job-evaluation plans, administration of, 79–91
    "above-the-curve" jobs, 84, 85
      methods for lowering rates of, 85

Job-evaluation plans, administration of, "above-the-curve" jobs, "present incumbent," defined, 84, 85
    principles for handling rates of, 84
  conclusions on, 90, 91
  market rates, 80–84
    change in, wage rates varying with, 81–83
    internal standards *vs.* 80
    key-job charting of, 80, 81
    market survey in determining, 83
      data and sources of data on, 83
    wage-rate surveys, 83, 84
    wage rates affecting, 84
      effect of changes in key jobs, 84
  objectives in, 79, 80
    job descriptions, importance of, 79, 80
      job-evaluation plan, 80, 84–86
      plan most popular in, 80
  "red circle" rates (*see* "above-the-curve" jobs, above)
  result checking of, 89, 90
  technological changes affecting, 86–88
    job reevaluation, 87, 88
    job simplification, 86
      wage-rate decrease due to, 86, 87
  union participation in, 88, 89
    basis for employee participation, 88, 89
    degree of, 88, 89
    discussion by union and management, 89
Job reevaluation and job simplification (*see* Job-evaluation plans, administration of)
Job scheduling, maintenance, 279–284
Job standardization, maintenance, 284, 285
Joints, silver-alloy brazing, 820–822
    clearances for, 821
    preparation of, 821, 822
    strength of, 827
  welded, types of, 797, 798

Linings, natural and synthetic rubber, 776, 777
Linoleum floors, 152
Liquid-piston-motor packing, 1369
Liquids, boiling, heat transfer, 1615, 1616
  flow of, through spring-loaded valves, 1830
Lithium chloride equipment for air conditioning, 665–667
Locomotives, gas turbines for, 509–511, 515
Logarithmic or exponential curves, 1796
Logarithmic mean, nomographic chart for, 1754
Logarithmic scale, 1694
Longitudinal vibrations, 1821, 1822, 1826–1828
Lubricants, extreme-pressure type of, 1323
  greases, 1312
    bases for, 1312
    characteristics of, tests for determining, 1312
        dropping-point method, 1312
        penetration method, 1312
    oil and soap requirements for, 1319
    types of (aluminum soap base, barium soap base, calcium soap base, lead soap base, lithium soap base, mixed base, sodium soap base), 1319, 1320
  oils, 1306–1312
    characteristics of, tests for determining (acidity and neutralization, carbon residue, color–value of, color conversion chart, demulsibility, emulsification, fire point, flash point, gravity, pour test, saponification number, sulfur content, viscosity), 1306–1312
    cylinder-oil characteristics, 1329, 1330
    refrigeration-machinery-oil characteristics, 1335–1337
    steam-cylinder-oil characteristics, 1325
  petroleum crude oil, 1304, 1305
    basic types of, 1304
    hydrocarbon classification of (aromatics, asphaltenes, naphthenes, paraffins), 1304
  petroleum refining, basic industrial costs of, 14
    refining procedure for, 1305, 1306

  s, 1338–1346
    properties of, 1338, 1339
      physical, available types of, table of, 1339
    silicone fluids, characteristics of, 1339–1343
    silicone greases, 1343–1346
      characteristics of, 1343–1345
      properties of, tables of, 1343
    special-purpose silicone greases, 1345
    special-purpose silicone lubricant, 1345
      pressure-lubrication of valves and flowmeters by, 1345
      water-insoluble characteristics of, 1345
Lubrication, 1303–1346
  air compressors, 1328–1331
    cooling methods affecting lubrication of, 1329
      aftercooling, reduction of explosion dangers by, 1329
      intercooling, protection of lubricants by, 1329
    cylinder oil, 1328–1331
      characteristics of, 1329, 1330
      requirements for, 1328–1331
    oil application, 1330, 1331
      control, 1331
      delivery point, 1331, 1332
  antifriction bearings, 1153, 1154
  ball and roller bearings, 1318–1322
    cleaning and flushing of, 1321
    function of lubrication for, 1318, 1319
    lubricant requirements for, 1320
    lubricants for, 1319–1321
      grease and oil, desirable properties of, 1319
      protection of, 1320
        seals for, importance of, 1320, 1321
    pressure-grease gun for lubrication of, 1322
      overlubrication dangers, 1322
  bearing design and construction, 1312–1315
    alignment, 1312, 1313
    oil grooving, 1313–1315
  chains, finished-steel-roller, 1055
      lubrication methods for various speeds (fpm), table of, 1055
    silent, lubrication methods for, 1067, 1068
      oil viscosities, table of, 1056
  circulating oiling systems, 1315–1318
    equipment for, 1316, 1317
    full-pressure lubrication, 1316
    oil protection, sealing methods, 1317, 1318
    pressure control, 1316
    pressure oiling by gravity, 1316
  gear-reduction units, 1092–1094
  of gears, 1322–1325
    cautions for, 1324, 1325
      alignment check, 1324
      oil-level check, 1325
    conditions pertinent to, 1324
    extreme-pressure lubricants for, 1323
      definite fields for, table of, 1323
    lubricant requirements for, 1322
    lubrication methods for (bath, force-feed, hand), 1323, 1324
    operating conditions, encased or exposed gears, 1323
    spur, helical, bevel, 1322
    trouble chart, table of, 1325
    worm gears, 1322
  reciprocating engines, external lubrication for, table of, 1328
  refrigerating systems, 623, 624
  refrigeration machinery, refrigerator compressors, 1331–1337
    cylinder wear, 1334
    methods of lubrication, 1332–1334

Lubrication, refrigeration machinery, methods of lubrication, gear pump, 1334
    mechanical force-feed oilers, pressure oiling, 1333, 1334
      cylinder and rod packing lubrication by, 1333
      vertical compressors with enclosed crankcases, 1333, 1334
    oil lantern, 1335
    oil pump, 1334
    pressure systems, 1333
      vertical or horizontal machines, large type, 1333
    splash oiling, fractional tonnage units and vertical machines, 1332, 1333
      piston-ring fit importance, 1333
  oil for lubrication of, 1335–1337
    physical characteristics of, 1335–1337
    requirements for, 1332
    viscosity, importance of, 1332
    water contamination of, 1336, 1337
  oil lantern for, functions of, 1335
  oil separator for, location and installation of, 1334, 1335
  stuffing-box seals for, 1335
silicone fluids, 1339–1343
  type A applications, 1339, 1341
    high-temperature mechanical devices, 1341
  type B applications, 1341
    medium to light bearing loads, 1341
  type C applications, 1341–1343
    hydraulic fluid, 1341
    nonferrous metal bearing surfaces, 1341, 1342
    torsional-vibration damping devices, 1342, 1343
silicone greases, 1343–1345
  special-purpose, 1345
    high-vacuum grease, 1345
    stopcock grease, 1345
  type I applications, 1343
    antifriction bearings up to 4,000 rpm, 1345
    high-temperature and corrosive conditions, 1343
  type II applications, 1343–1345
    antifriction bearings up to 20,000 rpm, 1343
    ball-bearing permanent lubrication, 1344
    electric motor bearings, 1344, 1345
  type III applications, 1345
    low-temperature lubrication, 1345
silicone lubricant for pressure-lubricated valves and flowmeters, 1345
steam cylinders, 1325–1328
  atomization of oil for, 1325–1328
  effective lubrication tests, 1326
    exhaust steam as guide, 1326
    imperfect lubrication, indications of, 1326
  lubricant distribution by steam atomization, 1325–1328
    factors affecting, 1326
    oil-introduction point, 1326
  oil for, 1325
    classification of, 1325
    viscosity of, 1325
    "wettability" of, 1325
  oil selection factors, 1327, 1328
    atomization improved by velocity, 1327
    moisture requiring compounding, 1327
      compounding, detrimental, 1327, 1328
    straight mineral oils for certain applications, 1328
Lubrication, steam cylinders, oil selection factors, temperature-pressure-superheat conditions, 1327
    quantity of lubricant required per 10-hr day, table of, 1328
  turbines, hydraulic, 588–590
    mechanical-drive, 607
Lucite, 1928

  theory, general, 1858–1861
    noise levels in buildings, table of, 1860
    sound, characteristics of, 1858–1860
Nomographic charts (*see* Graphical mathematics)
Nonferrous alloys, oxygen-cutting–powder-cutting process for, 846
Nonferrous metals, oxyacetylene welding of, 837
Nonuniform scale, graphical mathematics, 1694
Nuclear fission, 1683
Nylon, 1929

O

Office methods (*see* Supervision, tools of)
Offset, instrumentation and control, 701
Ohmmeters, static-ground testing by, 238
Oil, for generators, 228
  for hydraulic transmissions, 1287–1290
    head loss in pipes, 1288
      equivalent lengths of fittings, 1289
    maintenance of properties of, 1288–1290
  for transformers, 227, 228
    (*See also* Lubrication)
Oil-burner explosion hazards, 210
Oil coolers and filters for circulating oiling systems, 1316
Oil grooving for bearings, 1313–1315
Oil-lantern piston-rod lubrication, 1335
Oil motors, packings for, 1366
Oil separator for refrigerating compressors, 1334, 1335
Oiling systems, circulating (*see* Lubrication, circulating oiling systems)
Oily waste, fire hazards of, 231
  storage of, 231
Open-kettle temperature control (*see* Process control, automatic, applications of)
Open-mouth bags (*see* Bags)
Operating performance, incentive wage methods, 61
Operation charts, work simplification, 49
Organic acid recovery from plant wastes, 1594
Organic acids in plant wastes, neutralization of, 1597
Organic matter wastes, water contamination by, 1589, 1590
Organization (*see* Supervision, elements of)
  supervisory and wage-roll (*see* Maintenance fundamentals)
Oscillators, sonic, 1678, 1679
Otto cycle, temperature in air mixture, equation in determinant form for, 1775, 1776
Ovens, fire extinguishment for, 235
  fireproof construction of, 234, 235
  grounding of, 235
Oxidation, defined, 190
Oxyacetylene torch for silver-alloy brazing, 823
Oxyacetylene welding (*see* Welding, oxyacetylene)
Oxygen cutting, 837–847
  blowpipes for, 840, 841
    cutting nozzles for, 841
    premixing type of, 840, 841
    tip-mixing type of, 840
  cutting machines for, 841–843
    stationary shape-cutting type of, 841, 843
      magnetic templet for, 843
      strip templet for, 842
  cutting speed ranges for, table of, 840
  equipment required for, 840–843
  ferrous metals, adaptable to usual methods of, table of, 838
    and nonferrous metals cuttable by special techniques of, table of, 839
  gouging by, 847
  high-carbon and alloy steels, 847
    heat-treatment for, 847
      flame softening as, 847
  machine cutting, 844–846
    low-carbon steel, 845, 846
      circle cutting, 845
      multiface cutting, 846
      multiple-blowpipe cutting, 845
      plate-edge preparation, 846
      stack cutting, 845, 846
  machining by, 847
  manual cutting, 843, 844
    circles and irregular shapes, 844
    hole piercing, 844
  metal preparation for, 843
  operations possible in, 839
  oxygen lance for, 843
  quality of cut made by, 840
    "drag," defined, 840
  special techniques of, 846, 847
    cast-iron cutting, manual, 846, 847
    flux cutting, 846
  torches for (*see* blowpipes for, above)
Oxygen gas in tanks, 216
Oxygen-gas torch for silver-alloy brazing, 823
Oxygen gouging, 847
Oxygen lance, 843
Oxygen machining, 847

Packaged-materials handling (*see* Materials handling)
Packaging equipment, industrial, 1887–1901
  bagging equipment, 1890–1894
    container bag packer, 1898
    open-mouth bags, 1890–1892
      auger packers for dusty materials, 1891, 1892
      bag holder and scale for manual filling of, 1891
      bagging rates, 1890
      bagpak machine for weighing, filling, and closing, 1890, 1891
    valve-bag packer weight adjustment, 1894
    valve-bag packers, types of, 1892–1894
  case packers for canned and bottled goods, 1896–1898
  closing and sealing equipment, 1898–1901

- Packaging equipment, industrial, closing and sealing equipment, fiberboard boxes, 1900, 1901

  - and general services, gasket recommendations for, table of, 1376
    - rod-packing recommendations, table of, 1385

V

- V-belt drives, multiple, 996–1005
  - adjustment of, 996
  - alignment of, 996
  - center distance formula for, 999
  - operation of, 996
  - selection of, 997, 1004
  - service factors for, 1002
  - sheaves for, 1004, 1005
    - dimensions of, tables of, 1011–1016
    - face width of, table of, 1005
    - flywheel effect (WR^2) of, 1009, 1010
    - groove dimensions of, table of, 1004
    - outside diameters of, 1005
  - V-belts for, 996–1004
    - dressings for, 996
    - horsepower formula for, 1002
    - horsepower ratings for, tables of, 997–1001
    - length formula for, 998
    - quarter-turn, 1009
    - replacement of, 996
    - standard, 1003

- V-belt drives, multiple, V-belts for, storage of, 996
    - V-flat drives, 1007
      - correction factors for, 1008
      - selection of, 1009
  - variable-speed, 1006, 1007
    - horsepower ratings of wide range V-belts for, table of, 1006
    - selection of, 1007
    - variable-pitch sheaves for, tables of, 1008, 1017–1024
- V-flat drives (*see* V-belt drives)
- Vacuum, defined, 1458
- Vacuum control, 717
- Valve-bag packers (*see* Packaging equipment, bagging equipment)
- Valve control for hydraulic transmissions, 1297–1300
- Valve disks, 1359–1361
- Valve operation by gear reducers, 1105, 1106
- Valve seats, 1359–1361
- Valve stems, packing for, 1372, 1373
    - diaphragms as packings, 1396
    - sealing means for, 1372, 1373
- Valves, dry, 257
  - or heads for automatic sprinkler systems, 253, 254
  - magnetically operated, 1660
  - materials classification of, 737, 738
    - brass, cast iron, cast and forged steel, 738
  - silicone lubricant for pressure lubrication of, 1345
  - spring-loaded valves, flow of gas or liquids through, vibration, 1830
  - three-way diverting type for temperature control, 713
  - type classification of, 738–745
    - check valves, 745
    - gate valves, 742–745
      - disks for, 744, 745
      - operation methods, 742, 743
    - globe, 739–742
      - installation of, 741, 742
      - operation methods, 739, 740
      - seats and disks for, 740, 741
- Van de Graaff d-c generators for X-ray practice, 1631
- Vane pumps for hydraulic transmissions, 1292, 1293
- Vapor pressure, 1461, 1463
  - specifications for, Reid's, 213
- Vari-speed pulley, 1080, 1081
- Variable auxiliary, graphical mathematics, 1729, 1746
  - single, solution of equations containing, 1713, 1714
- Variable-speed fluid drives (*see* Fluid drives)
- Variable-speed machinery, vibration control in (*see* Vibration control)
- Variable-speed mechanisms, 1077–1088
  - manufacturers of, 1088
  - speed variation by, infinite or stepless, 1077
  - types of, 1077–1088
    - adjustable-cone-pulley, 1082, 1083
    - compound-adjustable-pulley, 1086
    - differential gear systems, 1086–1088
    - flat-belt, 1077, 1078
    - friction-disk or cone, 1078, 1079
    - interlocking-dual-pulley, 1081, 1082
    - PIV, 1083–1085
    - ratchet or interrupted-motion, 1079, 1080
    - steel-ring drive, 1085, 1086
    - vari-speed pulley 1080, 1081
    - VRD, 1084–1086
- Variable-speed V-belt drives, 1006, 1007
- Variable-torque electrical drives, 1206
- Variable-torque, lever-controlled, variable-speed fluid drives, 1267
- Variables, graphical mathematics, graphical method for charting relationship between, basic form of, 1781–1787
      - logarithmic scales, 1705
      - representation of relation between three variables, 1703–1708
      - uniform scales, 1704
  - instrumentation and control, energy, 678
    - process, 678–681
    - quantity and rate, 679
    - substance property, 679–681
  - process control, automatic, controlled and manipulated, 695
- Vehicles, automobile-body motions of, 1818
    - centers-of-rotation location for, 1818
  - shock absorbers for vibration control in, 1809
- Velocity-head formula, hydrodynamics, 1286
- Velocity-squared damping, 1799, 1800
- Ventilating-shaft fire protection, 208
- Ventilating systems, noise transmission through, 1861, 1862
- Ventilation, of buildings, air movement for, 1487, 1488
      - supply-outlet velocities for, table of, 1487
    - fresh-air requirements for, 1484, 1485
    - maximum allowable concentration of toxic fumes, table of, 1485
  - of flammable liquids and gases, 207
  - pressure-relief-dampers for, 1490
- Venting, explosion, dust-explosion prevention by, 220
    - explosion pressures, 210
- Venturi, 683
- Venturi effect, 1286, 1287
- Vibrating conveyors, 1413–1415
- Vibrating screens, 1560, 1561
- Vibration, 1797–1838
  - balancing machines for measuring, 1805
  - "chattering" of brakes and cutting tools, 1829
  - cylinder-in-trough system, 1802
  - definition of, 1841
  - dynamic vibration absorber, 1819, 1820
  - energy method, Rayleigh, for solving problems in, 1828
  - flow of gas or liquids through spring-loaded valves, 1830
  - "fluttering" of airplane wings and tails, 1830
  - forced, without damping, 1802–1805
      - dynamic unbalance, 1803
      - magnification factor for, 1804, 1805
      - resonance, 1804
      - rotating or reciprocating unbalanced mass as cause of, 1803, 1804
        - flexible shaft deflection, 1803
      - vibrating foundations as cause of, 1803
    - with viscous damping, 1805, 1806
      - amplitudes of, 1806
      - disturbing force and vibration, 180 deg out of phase, above resonance, 1806
        - in phase, below resonance, 1806
      - phase angles for, 1806
  - free, without damping, 1798, 1799
  - frequencies, natural, of elastic bodies, 1831–1835
    - of chain or cord suspended by one end, 1831
    - circular ring, 1833
    - lateral vibration of uniform bars, 1832
    - longitudinal vibrations in uniform bars or gas columns, 1831, 1832

INDEX

- Vibration, frequencies, natural, of elastic bodies, membranes, 1833, 1834
    - plates, 1834, 1835
    - stretched strings, 1831
    - torsional vibration of uniform bars, 1832
    - turbine disks, 1835
    - wedge, 1832
  - frictional-forces effect, 1799–1802
    - damping proportional to velocity, 1800, 1801
      - critical, 1801
      - less-than-critical, 1801
      - more-than-critical, 1800, 1801
    - dry friction, 1799
    - indicating instruments, correct damping of, 1801, 1802
    - velocity-squared damping, 1799, 1800
  - "hunting" or fluctuation of automatic control systems, 1830
  - lateral, of rotors, critical speed for, 1829
  - longitudinal, 1821, 1822, 1826–1828
    - bars, 1826, 1827
    - coil springs, 1826–1828
      - natural frequencies for, 1828
    - columns, gas or liquid, 1827
    - trains of cars, 1821, 1822
  - measurement of, 1805
    - instruments for, 1805
  - and noise in power-driven equipment, causes of, 1807
    - resilient suspension, spring mounting, for prevention of, 1807, 1808
  - noise, measurement of, 1813, 1814
    - instruments for, 1813
      - decibel scale, 1813
      - sound analyzers and sound-level meters, 1813
    - loudness of common sounds, decibels, table of, 1814
    - Weber-Fechner law of sensation, 1813
  - noise reduction in machinery, 1814, 1815
    - general principles of, 1814, 1815
      - mechanical filters, 1814
      - noise spectrum, 1814, 1815
  - nomenclature of, 1830, 1831
  - nonlinear systems, 1830
  - pendulum systems, compound pendulum, 1802
  - Rayleigh's method for solving vibration problems, 1828
  - resilient suspensions, spring mounting, 1677, 1678, 1807–1815
    - design difficulties, 1809–1815
      - conflicting rigidity requirements, 1811
      - frequency disturbances, 1812
      - spring design and materials, 1810, 1811
    - drop-forging hammers, 1811, 1812
      - elastic mounting of, 1811, 1812
    - motions possible, degrees of freedom, 1812
    - motors and machines, 1807, 1808
    - power drives, maintaining alignment of, 1813
    - vibration-transmission alternative paths, 1813
  - rocking-chair system of, 1802
  - self-induced, 1829, 1830
    - "chattering" of brakes and cutting tools, 1829
    - effect of dry friction and lubrication on, 1829
    - flow of gas or liquid through spring-loaded valves, 1830
    - "fluttering" of airplane wings and tails, 1830
    - "hunting" or fluctuating of automatic-control systems, 1830
  - single-cylinder mechanisms or reciprocating engines as cause of, 1809, 1810
    - balancers for single-cylinder mechanisms or reciprocating engines, 1809, 1810
- Vibration, single-cylinder mechanisms or reciprocating engines as cause of, balancers for single-cylinder mechanisms or reciprocating engines, Lanchester balancer, 1810
  - spring constants, 1835, 1836
    - linear and torsional, 1835, 1836
  - spring mounting for protection from, 1808, 1809
    - delicate instruments, 1808, 1809
      - transmissibility ratio, 1808, 1809
    - motors and machines, 1807, 1808
  - spring suspensions, 1807, 1808
    - effect of damping in, 1807, 1808
    - transmissibility ratio, 1807, 1808
  - systems of several degrees of freedom, 1820–1826
    - longitudinal motions of nonuniform masses and springs in straight line, 1822, 1823
      - remainder force, 1823
      - stationary point, "node," 1823
    - more complicated cases of, 1829
    - systems with uniform parts, 1820–1822
      - longitudinal vibrations in trains of cars, 1821, 1822
        - analysis of, 1821
    - torsional vibrations, 1824–1826
      - Lanchester damper for elimination of, 1825
      - torsional pendulum, floating counterweight, for elimination of, 1826
  - systems with two degrees of freedom, two natural frequencies of vibration, 1815–1820
    - beat frequency and beating, 1817
    - dynamic vibration absorber, dampers, 1819, 1820
  - time-variable systems, 1830
  - torsional, 1824–1826
    - internal-combustion or diesel and steam engines, 1825, 1826
      - Lanchester damper for vibration elimination, 1825, 1826
    - rotating shafts, 1824
  - unbalance in rotors, dynamic and static, 1805
    - correction of, 1805
  - vehicle suspension design, 1809
    - shock absorbers, double-acting type, 1809
    - vehicle springs, 1809
  - vibration transmission by power-driven machinery, alternative paths for, 1813
  - vibrations of bodies with distributed mass and elasticity, 1826–1829
    - "critical speed" for lateral vibration of rotors, computation for, 1829
    - dynamically equivalent systems, 1829
    - energy method for solving problems of, Rayleigh's method, 1828
    - longitudinal, in bars, coil springs, and gas or liquid columns, 1826–1828
- Vibration control, 1839–1858
  - applications of, practical, 1852–1854
    - reciprocating engines and machines, 1852–1854
      - spring-isolated concrete foundation for mounting of, 1854, 1855
      - type of unbalance from, 1853
    - rotating equipment, 1854
  - benefits of, 1841
  - constant-speed machines, 1847–1850
    - damping effect, on relative magnification factor for various frequency ratios, 1847
      - on relative transmissibility for various frequency ratios, 1849
    - undamped systems, 1847–1849
    - viscous damping effect, 1848–1850
      - transmissibility for damped system, 1849

- Vibration control, general theory of, 1840, 1841
  - impact machinery, 1854–1858
    - isolating materials for, efficiency of, 1857
    - spring-isolated hammer foundation, 1856
  - instruments used in solving vibration problems, 1678, 1842–1844
    - acceleration-measuring, 1843, 1844
      - accelerometers, 1844
    - frequency-measuring, 1843
      - stroboscope, 1843
      - tachometer, Frahms type, 1843
    - vibration-measuring, 1843
      - "seismic" vibrometer, 1843
      - vibrograph, 1843
  - laboratory equipment, 1858
  - machine tools, 1858
  - mechanical vibration, noise due to, 1862, 1864, 1866
    - isolation for control of, 1862, 1866
      - "floating" bases, 1866
  - nomenclature of, 1840
  - terminology in common use, definitions of, 1841, 1842
  - variable-speed machinery, 1850–1852
    - damped system, 1851, 1852
    - damping effect, on absolute mangification factor for various frequency ratios, 1851
      - on absolute transmissibility for various frequency ratios, 1852
    - undamped system, 1851, 1852
- Vibration-control theory, 1844–1847
  - frequencies, 1844–1847
    - disturbing and natural, 1844
      - static-deflection, natural-frequency relation, 1844–1847
  - isolation efficiencies, 1844–1847
  - undamped systems, 1844–1846
    - deflection-frequency relationship for, 1845
    - vibration-isolation efficiencies for various natural and disturbing frequencies in, 1846
  - viscous damping, 1844, 1845
